JUDGMENT FOR NOMINAL DAMAGES FOR MALPRACTICE REVERSED

In an action for malpractice it was established that defendant surgeons inadvertently left a gauze sponge within the incision after the removal of a kidney. On the point whether injury resulted from this there was much conflicting evidence. The jury rendered a verdict for plaintiff, awarding him, however, only nominal damages. The Kansas Supreme Court, Russell v. Newman, 226 Pac. 752, two judges dissenting, reversed judgment thereon, holding that the leaving of the sponge in the incision undiscovered for 70 days must have resulted in substantial damages notwithstanding the testimony of physicians to the contrary.

The Eugenic Program—How Far Is It Practical?

THEODORE DILLER, M.D.
Pittsburgh

The socalled science of eugenics, which has for its large object the improvement of the human race, has in recent years attracted the interest and enlisted the support and energy of a growing number of persons and organized societies throughout the world; and the recent International Congress on Eugenics held in New York bears witness to this widespread interest. Oddly enough the medical men have not exhibited the interest in this subject which is in keeping with our numbers and the importance of the subject. However, an increasing number of leaders in our profession have investigated the subject of late, among them Dr. Lawrence Litchfield and Dr. William Allen Pusey. The medical profession may now well ask itself what, if any, attention and interest shall it pay to this subject, and what, if any, method of investigation shall it inaugurate?

In *Mankind at the Crossroads,* Professor Edward East, of Harvard University, goes over the whole subject; and since he, I believe, pretty well represents the nonmedical point of view, a very brief review of his book may best serve my purpose in introducing the discussion of the subject on my own part.

Professor East tells us that whereas there were five million persons in the United States in 1800 there are now one hundred and ten million, and while in 1800 the population of the world was fifty million it is now one billion seven hundred million; and in another two hundred years there will be five billion persons in the world—the limit of population it can support. He refers to the intelligence test conducted by the army and accepts the conclusion that there is a large percentage of incompetent and subnormal persons in this country. He points out the decrease in the birth rate and the decrease in the death rate, which he says about balance each other. It is well known that the incompetent members of the community are increasing far more rapidly than the biologically competent members. The human race is to be improved by teaching fully and completely the doctrine of heredity, and men and women must be taught how better to mate with regard to the production of offspring. The mentally unfit must be segregated or rendered incompetent by castration.

His main argument, however, to which he returns over and over again, is the subject of birth control. The facts must be spread before the people and then the biologically competent must produce more children and the biologically incompetent must produce less. The whole thing is one of education and the taboo of theology and the fantastic law enacted through the influence of Anthony Comstock, must be repealed so the way may be cleared for a campaign of birth control which must be nationwide, indeed worldwide. It can succeed only by united action.

And then Professor East, after going through twelve long chapters in 351 pages, concludes his book with these significant lines: "Today the finest families are hardly replacing themselves. The incompetent are taking their place. And this will continue should there be no eugenic reform until that point of equilibrium is reached where no more dolittles can be accommodated. . . . Half the people in the world lack sufficient brains to cope with the intricate system of social life the industrial age has brought about. . . . Knowledge to prevent the decay of our social fabric is not wanting; but it is a serious question whether there is the required amount of that type of ability which will make a sustained effort to apply it."

Thus it appears to me his argument is academic, utterly lacking in force, indeed, selfcontradictory. After convincing himself and attempting to convince his readers of the vast amount of mental incompetency there is in the world, he then advocates a program which requires great mental competency on the part of the community. And sadly enough the very last word of his book is a weak one and one of doubt. He asks, "Is there the required amount of ability to make sustained effort and apply our knowledge?" Here, like many pedagogues, Professor East makes the highly erroneous assumption that if we know a thing we will do it. Whereas every student of Nature knows that with knowledge and ability a thing is not done unless there is a *desire* to do it. Everywhere he speaks of knowledge and ability, where he should speak of desire.

Recently I have read many books and reviews on the subject of eugenics; the familiar argument appears to be repeated in all of them. The unfit must be eliminated. This is to be done by a knowledge of heredity, the desire for better children, segregation or sterilization of the unfit, and above all, birth

*Read before the Pittsburgh Academy of Medicine, December 23, 1924.

Copyright, 1925, by A. R. Elliott Publishing Company.

control. For instance, one author writes a long paper in which he argues that "All superiors should mate" and he adds, "with each other." Thus finally he would eliminate all of the unhappiness in the world. He warns against selection on the basis of beauty and vivacity alone and brings to the fore, poise, endurance, stability and judgment. He denies that a man marries an inferior that he may retain his leadership, but says the more capable the mate the more stimulating. Making against selection of high grade parents is the training of young women in colleges when they are at the impressionable age when marriage commonly takes place. To overcome this the author suggests all colleges shall be coeducational so the fit may thus select the fit. Another writer suggests that a eugenic bureau be established in every town to furnish a eugenic history to men and women contemplating marriage. So it goes. And more like this.

While we have heard a good deal of birth control in this country it would appear that the subject has been discussed much more largely and with greater warmth of feeling in Great Britain. The *British Medical Journal* says: "A conviction has steadily grown that the advocates of conception control and their opponents are for the most part tedious writers, only to be tolerated if the views they uphold or denounce with so much vehemence are really of first rate importance." Many of the articles seem so fantastic, many of them are so dull by repetition of articles before them, that I can understand very well our sensible British friends becoming wearied of the whole subject. However, I wish to pay a tribute to Major Darwin (son of Charles Darwin) who presided at the Eugenic Congress and who apparently appreciated the whole situation and trend of the discussion and solemnly warned against impractical visionary and fantastic programs. He himself only felt sure of his ground that it was wise to stress the subject of heredity and its great and significant importance. He said we could be sure of our ground in trying to teach teachers that in mating people should take into consideration health, heredity and the possibility of offspring.

The subject of birth control was discussed by Dr. Pusey last June in his presidential address before the American Medical Association. He expressed sympathy with the desire that by better breeding the race should be improved. He then said: "I desire particularly that the mistaken impression should not go out that I mean to say that medicine now has any satisfactory program for birth control. It has not."

Recently the Committee on Maternal Health of the New York Academy of Medicine has been investigating this whole matter, basing their inquiry upon the findings in several hospitals in which five thousand cases were considered and a study of the literature. This report is noteworthy and one which medical men may well consider. This committee states that there has been no investigation of birth control made in a scientific or ethical spirit approaching the subject without bias. It also states that in Holland, which is so often quoted as the paradise of birth control, it is "without clinics, clinical reports or consensus of opinion." The committee concludes that the medical profession does not yet know any guaranteed contraconceptive. Now Mr. Udny Yule comes forth in an editorial in the *British Medical Journal* in which he makes the statement, based on studies both British and American, that the growth of population is a biological selfregulating process; indeed a process in which regulation is extraordinarily sensitive. "This conclusion rejoices the *British Medical Journal,* which hopes it is true so that advocates and opponents of birth control may be left to talk to themselves and let other people alone who are weary of the subject."

We must remember at the outset of any discussion on eugenics that while the human race is subject to biological laws, it is, whether we like it or not, also tied and under the guidance of moral, religious and political laws, and these to some extent contravene biological laws. So in any discussion of the improvement of the human race we must bear this in mind. If it were possible to consider the matter from a biological viewpoint alone, without moral or political considerations, one would immediately without reserve advise the killing instead of the segregation of the unfit. Thus the problem of the propagation of the unfit would be largely solved in the beginning. But as things actually stand in organized civil society, there is unanimous feeling against taking the life of anyone except rarely for crime, no matter how incompetent or how incurable they may be; and then there is unanimity that abortion must not be committed except rarely in certain circumstances where the life of the mother would be jeopardized. These are things for which society, the church, the state and the medical profession stand with great unanimity.

But when we come to birth control, we do not find anything like this same unanimity. And in view of the evidence we have at the present time the medical profession ought to go very slowly in this matter and not be hurried or pushed into it by enthusiastic social workers or humanitarians. It is a serious matter to take human life in being; it is a serious matter to produce abortion; I submit it is also a very serious matter for a physician or social worker to undertake to tell men and women when and how many children they may have. It seems extremely doubtful that this can be done; and if it could be done, it would seem to me it would be a thing we ought not to attempt to do. We must bear in mind that the question of birth of children in the family, while a medical matter, is also far more than a medical question. It is a political question, it is an economic question, and a moral question. It would be well for us to bear these facts in mind in any discussion of this matter.

Moreover, I feel that when the medical profession speaks on this subject it should be with unanimity, like that in which it speaks now on the subject of abortion. By all means let us discuss and investigate, especially along the lines indicated by the New York Academy of Medicine; but for the present let us bear in mind Dr. Pusey's admonition that medicine has not now any safe program for birth control.

The tendency of society today is to promote what Fauget calls the cult of incompetence, that is, the tendency to foster mediocrity at the expense of competency. Society carefully conserves the weakling and the incompetent of all sorts. We have our jails and our hospitals for the insane, the crippled, the

blind and the deaf. And in recent years society has entered upon a much larger program, and social workers of all sorts care for the aged, the mothers, helpless children, etc. In these socializing forces I believe there is danger, grave danger. There is the danger that the persons helped will expect more and more help and to lean more and more. Since we are committed to the policy of caring for the unfit, we ought, for their sake and for our own, to call some reasonable halt on the number of things for which help may be given and the extent to which help may be extended the unfit. Dr. Pusey points out this thing has developed so that for eleven workers over sixteen years of age one is supported as an employee.

Well, what can be done in the matter of improvement of the human race? Can anything be done? Personally I believe with Dr. Pusey the law of the survival of the fittest cannot be greatly modified, nor long set aside, and I am strongly disposed to accept as correct the view of Mr. Yule that "the growth of population is biologically a selfregulating process. Then what is practical and workable in the eugenic program? It is not practical to terminate the life of the unfit, nor is it practical to perform abortions on unfit women, nor is any program of birth control, which has been suggested, practical. But I believe with Major Darwin that it is practical to teach teachers more fully the value of health, and the great value of a selection of healthful partners with regard to the matter of offspring. The biologically fit should be encouraged to mate and beget children. While I do not expect much from this, I think it may help a little. Segregation and castration of the grossly unfit has been proposed. There is a widespread feeling against castration; it would appear that it is practically a dead letter law in the states where it has been passed. It is a thing to be advocated perhaps; but the good accomplished by it must be infinitesimal.

There is much larger hope for the good effect of the segregation of imbecile and feebleminded women of childbearing age. The State of Pennsylvania has begun a program providing for this very thing. It has established an institution at Laurelton for feebleminded women of the childbearing age. This institution now accommodates actually three hundred women and I am informed by those in authority that three thousand women in the state could well be placed there to the advantage of the Commonwealth. Here is a eugenic step that appeals to me strongly as not being visionary, but most practical, and which is not likely to promote discussion engendering heat without light. Let us use our influence, so far as we have it, with the next Legislature to provide means to expand this excellent institution, so that it may accomplish this good thing for which it stands.

But there is one thing further which is not often discussed in eugenic programs, which I believe is one of great practical importance for our own country, and that is, the subject of immigration. Heretofore, our immigrants have come from northeastern and central Europe, whereas in recent years they have come largely from southwestern Europe, a far lower grade of people, generally speaking, as indicated by their appearance, conduct, and by intelligence tests which have been made. I believe, as medical men, we can support in general the restrictions which our government has established and I would even go further and allow a greater increase of immigration from northern Europe from races which are akin to the old stock in this country, I mean those from the British Isles, Scandinavia, Holland, Germany, and Switzerland.

SUMMARY

1. While there is much that is fantastic and visionary in many measures proposed in the name of eugenics, the thing for which it stands—improvement of the human race—deserves and should enlist a growing interest in the medical profession.

2. Among things impractical in eugenic programs in civilized society are these: a, killing of the unfit; b, promotion of abortions; c, birth control.

3. Plans that are feasible and practical today and which should enlist the sympathy and aid of the medical profession are: a, teaching of rules of health and heredity as regards mating; b, encouragement of the fit to mate and the unfit not to mate (very little may be expected from this); c, segregation in institutions of feebleminded women of the childbearing period; d, support of our present immigration law and the use of our influence to bring to this country the people of north and western Europe and especially those that speak the English language; discouragement of immigration from southern and eastern Europe.

The Outlook for the Tuberculous Patient*

HENRY C. SWEANY, M.D.,
Chicago, Ill.

Perhaps it is presumptuous to attempt to give any opinions regarding the future of anything scientific, yet there are certain signs clearly imprinted on the pages of the past that may guide us in making a few statements regarding the possibilities and even some probabilities concerning the trend of events in tuberculosis work. Disclaiming anything that has the appearance of prophecy, let us review the past of tuberculosis and ascertain what bearing it may have on future developments.

A very significant fact regarding tuberculosis is that it has been with the race since remote antiquity. How far back we do not know exactly. Moody (1) produces evidence of an unquestionable Pott's disease in a skeleton of the Neolithic age and regarded by Bartels as the oldest specimen of that disease. There is another reference (2) to a mummy of a priest of Ammon in Egypt about 1000 B. C., where Pott's disease was associated with a psoas abscess. During very early history there are numerous references in Chinese, East Indian, Hebrew, and Greek

*From the Municipal Tuberculosis Sanitarium, Chicago, Ill.

literature which indicate beyond question that the disease was well disseminated by the beginning of the historic era. From these meagre data we may speculate that during the glacial periods perhaps, or later, when man first began to congregate in caves and shelters, tuberculosis came in as Nature's rude protest against such an unnatural mode of life; at least unnatural for men who had been reared in open air and sunshine. Indeed we may draw a direct analogy in recent times. The North American Indians, even after a thorough contact with the white race, did not begin to develop tuberculosis until they began to forsake their native customs. Benjamin Rush (3) as late as 1794 states that "pulmonary consumption is unknown among the American Indians." The committee appointed by the National Association (4) October 28, 1921, to investigate tuberculosis among the North American Indians reported that the Indians have undergone a gradual tuberculization due partially to the depletion of their wild food supply and an enforced change of habits of living resulting therefrom. There were other factors, such as a lack of immunity, but the big thing was the change from the outdoor to the indoor life, with insufficient food.

Through this lapse of many centuries, tuberculosis has been a constant associate of man, sometimes gaining, sometimes losing, but on the whole entrenching itself into the most remote corners of the earth. It has been active since historic times almost in proportion to the activity, congestion, and industrialization of civilization. It is certainly an unpleasant but truthful statement that it is a child of civilization. The fact is, that civilization carries with it certain requirements of mutual association and contact that enhance the growth of destructive microorganisms, which was not provided for in the early development of the race. It remains now for the race to meet the emergency in the new environment and in the rapidly changing environments of the future.

From a retrospect of the long drawn out back and forth struggle of tuberculosis and man, no one is so optimistic as to predict a cessation of the conflict in the near future. First of all, we must admit that it will be a fight to the finish against a deaf and dumb foe. We must also admit that even in the most scientifically regulated communities, such as the Framingham experiment (5), that the disease is not yet completely controlled. If such is true, how about the remote communities, in which little or no effort is made toward control? We know that the world is rapidly becoming more congested and more industrialized, and against this we must make a continual realignment of our forces to meet the changing situations. We know that intemperance, exhaustion, overwork, and dissipation are predisposing factors and that it is only a meagre minority who follow strict hygienic rules of living. We know that privation, hunger, and worry also cause it, but the "poor will be with us always." Furthermore, we know that diseases of many sorts play an important rôle, but when are we to be free from disease? Finally, assuming that every community will eventually be able to wipe it out by a combined effort, we shall continually experience social and political upheavals that will unbalance and disorganize the forces that control it, and may even result in an armed conflict which at the best is worse than all the atrocious conditions aforementioned.

Starting then with the idea in mind that the tuberculosis fight is to be a long one, let us take up one by one the factors which play a rôle in the struggle.

NATURAL DEFENSIVE MECHANISM

Even before the race knew what the disease was, natural means of defence against the infection were being developed, first, by an attenuation of the virulence of the microorganism, and secondly, by an increased immunity of the individual, which after a generation or two is transmitted to succeeding generations and may be termed racial immunity.

ATTENUATION OF VIRULENCE

As to the attenuation of the virulence of the organism we have an analogy in certain other infectious diseases, which gives us some hope. Syphilis does not seem to be as virulent as in the days of the "Neapolitan scourge." Neither does leprosy appear to produce the disastrous results that are described in ancient writings. While we have evidence that tuberculosis on the whole is not perceptibly losing its virulence, there are isolated instances where the bacillus has gradually retrogressed until it has become a saprophyte. The original R.1 of Trudeau is such an organism and everyone working with the tubercle bacillus has noticed that after about two years of artificial cultivation it begins to require increasingly larger doses to kill guineapigs, until after seven to eight years it will produce only local tubercles. But so long as the organism is transmitted from host to host, as tubercle bacilli are, there are rare cases of attenuation of virulence. Corper (6) found only three per cent. of bacilli isolated from specimens of pulmonary tuberculosis of reduced virulence. Griffith (7) in his splendid reports on the bacteriology of various forms of tuberculosis has shown that the organism appears to lose its virulence only when it becomes localized in the skin, bone, glands, etc., for any period of time, but less than one per cent. of internal infections were of reduced virulence. These external types of infection are rapidly disappearing, due to protection afforded by food inspection and surgical measures, so that the pure pulmonary forms are predominant and therefore it appears that the virulence of the tubercle bacillus will be sustained indefinitely.

IMMUNITY

Space will not permit complete details of the immunological phenomena resulting from the ordinary infection as contracted, both on the individual and his progeny. There is no doubt, however, that such immunity is the saving grace of the human race, for without it, especially when no modern sanitary measures are used, races perish when once inoculated with the tubercle bacillus. After infection, aborigines will present an acute "infantile" type of disease and will succumb rapidly with a generalized infection. Some immunity is being conferred, however, for after a generation or two the infection does not run such an acute course, but assumes more the "adult" type of disease or in fact may produce only localized glandular lesions which in turn give added protection to succeeding infections. Therefore by a

subtle method Nature has immunized the individual and has gradually added immunity to his offspring until the race itself becomes partially protected, so much so, that the infecting and disease producing dose is larger, the course of the disease is wholly changed, and in most immunized races about one per cent. of the infected succumb and only about ten per cent. of these die.

NATURE OF INFECTION

In order to understand properly the reasons for these phenomena, it will be of assistance to explain briefly tuberculosis infection. It is now pretty generally agreed that most people are infected in childhood. Krause (8) has compared the work of Hamburger and Pirquet in Vienna; Mantoux in Paris; Moro in Munich; Veeder in St. Louis, and Armstrong and Bartlett in Framingham (Mass.), and has shown the striking similarity of their results, which demonstrate in a not uncertain way that city folks are infected very young. Ghon (9) in Europe and Opie (10) in America have corroborated this pathologically. In addition there is much more to this early infection than an acquisition of the bacilli. Therein lies the basis of much adult disease; according to the Von Behring theory most of it. There are many others, among whom is Bushnell (11), that subscribe to this theory wholly or in part. Krause (12) feels that this point is not adequately proved although no doubt a great part of adult infection arises from a flareup of the childhood infection instead of "reinfection from without." Instead of the dust, droplet or milk infection predominating, Krause feels that much childhood infection is acquired from raw sputum from obscure cases of tuberculosis. This is sound doctrine. Just as the races that are in closest contact and in the greatest activity become infected, the children represent this activity squared. They are here, there and everywhere. If a consumptive even touches any furniture with contaminated fingers, the child has numerous chances to touch this same place and subsequently transmit the infection to its own mouth. Those who understand bacteriology, can readily see that in an open case, where the patient is passing bacilli over his lips by the billions every time he expectorates, a few are bound to stick to the lips and be wiped off on the fingers, to be transferred to the furniture or other objects.

Nothing has been said of the numerous things that may modify these early infections. Without going into the various phases of environment, so admirably given by Krause (13), we shall mention a few of the more general factors that influence infection and immunity in tuberculosis.

SUSCEPTIBILITY TO INFECTION

There is a great variability of susceptibility to tuberculosis in different age groups which we shall consider briefly. Tuberculous infection from infancy to old age runs a progressive course in the socalled immunized peoples. The infant has no allergy and for some unknown reason its lymphoid tissue does not respond to the toxins of the tubercle bacillus so the bacilli after once getting into the lymph stream of the lungs passes readily through and will form tubercles in distant parts of the body, having a tendency to form general miliary tuberculosis. As the child gets older, three to thirteen years of age, its lymphoid tissue appears to react more and thus do we get the glandular types of childhood. The hypermotility of the pulmonary structures assist in mobilizing the organisms in the gland depots. Then from thirteen to twenty years, there is the development of allergy together with a decreased lung motility which tends to arrest the bacilli in the lung parenchyma near where it first lodges and the adult type of disease results. In old age the allergy seems to be present, but there seems to be a tendency to call death due perhaps to poor circulation that enhances the growth of the tubercle bacillus.

INFLUENCE OF INDUSTRY

Another major factor is the influence of modern industry. This question is ably dealt with by Collis (14) who states that the death rate in Sweden during the early part of the last century was relatively low and the time of maximum incidence was fifty years of age or over. But when modern industry and better means of communication came in after 1870 the death rate rose considerably and the age incidence was shifted more into the young adult life from which the greater portion of the laborers are drawn. Similar statistics for Ireland, Scotland, England and other European countries are given and all indicate the profound influence that industry bears on tuberculosis incidence. To clinch the argument he uses the figures of incidence for females during the war in which the increase is very striking.

The converse of industrialism, or agrarianism, may be cited as a factor having a beneficial influence on infection. This is borne out by statistics from the agricultural districts of North America where the death rate falls far below fifty in a hundred thousand.

Finally, we wish to mention the influence of starvation upon large masses of people. Witness the increased death rate in Germany following the war where the immunity was certainly not greatly different than before, yet as Emerson (15) points out, because of privations and a break down of their organizations, the death rate from tuberculosis almost doubled for a time. Conversely, the nation that has the best tuberculosis organizations and is the best fed will produce the lowest death rate, all things else being equal.

NATURE OF IMMUNITY

The greatest significance, however, of infection in general and particularly of early infections is that they confer a hypersensitiveness or allergic properties to the cells of the host that bears a quantitative relation to the liberated tuberculotoxins until the organism becomes overwhelmed. This allergy accounts for the Koch phenomenon, the focal reaction and numerous other phenomena of tuberculosis. No mention is made of humoral specific antibodies because they do not assist materially in the defence of the organism in tuberculosis. Therefore we may disregard them.

In order to make these phenomena as clear as possible in a few words, the work of Krause (16) may be cited because it embodies nearly all the principles of earlier work. As a sort of summary, we

may state that the inoculation of an already infected individual will cause a "focal reaction" tending to liberate toxins from the foci of infection which may cause various results depending on dose, environment, and the amount of infection present. In small doses a previous infection tends to prevent the spread of subsequent infections, but with large doses and with active disease present, there will be sloughing at the site of inoculation and the focal reaction will be so violent that in active cases the tubercles will be broken down and the disease will take on an exudative character. With small doses, however, in sensitized subjects reaction develops at the point of infection, an inflammatory capsule will result and the bacilli retained locally where a local tubercle will be formed and the bacilli kept from spreading until they are destroyed. This is what happens in the vast number of persons who become immunized by infection, yet the protection is not enough to insure against massive doses and is not enough to prevent the primary infection from slowly smouldering into activity under provocation. Furthermore, these individual infections gradually confer more protection until the whole race eventually acquires it.

RACIAL IMMUNITY

As mentioned before, primitive races gradually became tuberculized with a corresponding change in the type and severity of the resultant infections. Drolet (17) has shown recently that the offspring of the tuberculous are less prone to contract the disease than are other people, thus confirming the belief that infection confers defensive properties that are transmissible to the offspring. This apparent increase of resistance when considered over a long period of time we may term racial immunity or racial tolerance. It is really a cumulative effect of individual infections in successive generations and is the quality in the tuberculous that activates the proliferation of fixed tissues (connective and reticular) about the focus of infection. This fibrogenesis and the hypersensitiveness called allergy are responsible for the common pathological and clinical manifestations that we find in the adult type of disease today; the former causing proliferative and the latter exudative changes. Fibrogenesis may be considered as a function of regularly repeated exposures during the past, while allergy is a function of existing infection. When allergy develops in these partially immune people, with moderate doses, there will be a rather rapid encapsulation; but when it develops in a primitive race the result is the strictly exudative type of tuberculosis, such as pneumonia and meningitis. In fact, it is easy to point out the races of people that are now or have been in the centres of the greatest commercial activity, especially when considered with the industrialization of the world. According to Drolet (17), "the present lesser and decreasing amount of tuberculosis among the Jews, the Italians and the English, all stocks that have known town and city life longer and a greater amount of infection than, for instance, the descendants of agricultural stocks, or those living formerly in the open air, like the Irish, the Scandinavians, the Negroes and the Indians, can also be better understood." The value of this work rests on the fact that all the races reported were in the same city under similar general condition. The only thing to be desired is a like comparison of subjects of the same races, in the same city, following the same line of work, and having the same home conditions. It is doubtful whether the results would be materially altered. For example, the Swedes and Italians are both chiefly engaged in construction labor and the home life of the former may even be better than that of the latter, yet the tolerance to tuberculosis is greater in the Italians. The Irish who seek out occupations as policemen, railway men, etc., have a high death rate, yet these occupations have a very low death rate among other races. The French and, according to Coni (18), the Spanish are chiefly engaged in kitchens, bakeries, offices, etc., yet their death rate is about double that of the Jews, who are also shop owners and inside workers, even though the home life of the former is probably on the average above that of the latter. The Jews who have been in the thick of civilization for three thousand years produce an example that is unique and might well be the subject for a whole discourse alone. From these data it seems that we have incontrovertible evidence of a cumulating racial immunity.

One thing further must be said about racial immunity and that is that it is lost when a race withdraws from the active channels of industry. In fact, there is no doubt that races have drifted back to the pastoral life and lost the infection and the immunity completely, only to be reinfected again when modern industrialism has come in. Persia (19), the Soudan (20), Egypt (21), Greece (22), and perhaps India are all examples of communities in which tuberculosis once thrived, but today it manifests varying grades of racial reinfection with a loss of former immunity. It must be borne in mind, however, that this cannot be used as an argument in favor of the spontaneous disappearance of tuberculosis. It would be possible if the world were large enough to allow everyone to follow a pastoral life, but the big cities are here to stay and so is industrialism and rapid communication. These facts alone insure a long sojourn with tuberculosis. As it is, these nomadic peoples simply furnish fuel to the fire when they reenter the active theatres of civilization.

We can see that potent as individual and racial immunity is, it is by no means adequate to stem the onrushing tide of tuberculosis, even barring the future increase in congestion and industrialization.

ARTIFICIAL DEFENSIVE MEASURES

A different phase of the subject is that of artificial defensive measures or those that have been brought about by the intellect of man. These factors may be summarized under the headings of social measures, public health measures, and laboratory research. They will be dealt with in order.

SOCIAL MEASURES

After the scientific investigators had pointed the way to prevention, it remained for someone to carry out these measures in practice. Societies for prevention, therefore, sprang up all over the civilized world, among which was our own National association. It is difficult to evaluate the comparative service rendered by the army of workers engaged in the social aspect of tuberculosis, but in volume of work

done, lives saved, finances raised, it unquestionably ranks first. In fact, tuberculosis has been called a social disease and not without reason, because the bulk of activities in its prevention is a social problem. The great decline in death rate has been largely due to these activities because all the early diagnoses possible would not lower the death rate materially if there were not a constant effort to stop the disease at its source.

The propaganda of education spread among the working classes by the various associations for the prevention of tuberculosis has slowly but surely been taking effect. Working conditions have been improved, the old sweat shops are gone, with airy, sunny factories in their places. Workmen are protected in hazardous occupations, working hours are shorter, living conditions have been bettered, and poverty has been reduced; thus the "soil" for tuberculosis has been removed. People have been taught the dangers of infection and the methods to prevent infection. The true nature of the disease has been taught. The patients have been followed up after recovery and have been placed in occupations suitable to their physical condition. Last of all, the various organizations have been united so that a more perfect liaison between the various organizations will result.

Notwithstanding all this, there is still room for improvement and no doubt much more progress will be made to meet the increasing production of tuberculous "soil." There is absolutely no hope, however, that this means alone will wipe out the disease. There will always be dissipation, poverty, congestion, and increasing industrialism—the soil; and, as we pointed out previously, there is no likelihood of completely destroying the seed. This is further borne out by the fact that in cities today we all receive on the average at least one infection before ten years of age. Perhaps there are many during our whole lives. These small doses help to give us a partial immunity to the disease. Assuming that the open cases and sources are wiped out so that we get but few infections, soon the disease will revert to the form found in primitive people, and continual "epidemics" of tuberculosis will result.

PUBLIC HEALTH MEASURES

Of all the measures aimed against tuberculosis there is none at present with the potentialities of the public health organizations. These organizations have an enviable record in practically wiping out bovine tuberculosis by the inspection of cattle and meat, and the pasteurization of milk. They are also in a point of vantage against human infection, although they cannot use the same measures against this type that they have used against the bovine. Such measures as the destruction of septic material, sputum, etc., the ordinances against spitting, the reporting of open cases, have been remarkably successful. The forcible hospitalization measures have met with some difficulty in enforcement. Yet, there is no better means today of lowering the death rate than a vigorous but humane application of such measures. This work is yet in its early stages and it is doubtful if it ever can be applied to its maximum efficiency. For example, there is little advantage gained on the whole in enforcing these measures in one community and not in the surrounding ones. Perhaps it might eventually work out satisfactorily, as the neighboring community would soon learn that it must follow suit to prevent its becoming a dumping ground for all the undesirable tuberculous patients.

First of all, it seems that a more persistent attempt should be made to educate people to live more hygienically, beginning in the public schools, if possible. The necessity for enforced hospitalization is not apparent to a large mass of people because they cannot understand why tuberculosis should be looked upon as such a plague now since it has been a "household pet" for so long. A thorough campaign of education, beginning in the public schools, will greatly simplify the problem.

After an adequate educational campaign the law could be made more drastic and progressively applied more vigorously. This is the attitude taken in Germany (23). Heitmann in Norway (24) and Hunziker in Switzerland (25) have drafted new laws that are extremely drastic yet comprehensive. An important feature in both laws is the compensation for the isolated patient. As Heitmann says, "It is obvious that if a person is deprived of his means of livelihood to benefit the public, it is the public's duty to see that he is not rendered destitute." Some such a plan may be made operable, because the incorrigible patient could then be deprived of his allowance if he became unruly. For just like every other group of people, there are some tuberculous patients who do not understand any language except a "law with teeth." Perhaps some such provision would render the law more operable here in America, where anything that appears to interfere with personal liberty is looked upon with great suspicion.

Probably the greatest practical service in the past has been the work of sanatoria and dispensaries where patients are treated, educated in their disease, and taught their duty to themselves and others. As Watterson (26) says, "the sanatorium should be the training camp for the war on tuberculosis." Starting with the work of Brehmer and Dettweiler in Germany in the middle of the last century and followed up by Patterson in England, Trudeau in America and a host of others, every municipality is establishing their sanatoria for tuberculosis. As to the methods of treatment little improvement can be made, but there is great need for more institutions and more education for patients in the institutions.

LABORATORY RESEARCH

While the actual work in the field is done by social and public health organizations, we must not underestimate the rôle played by the laboratory. The laboratory may be called the pacemaker for the other activities and without it there would be little advance. Not until such men as Laennec in the beginning of the nineteenth century pointed the way, was there any change in the method of handling tuberculosis. Laennec, who died of tuberculosis, firmly believed that he had contracted the disease at the postmortem table. While not understanding infection as we do today, he made most accurate descriptions of the gross pathology of tuberculosis—the cavity, the walls, the development of the tubercle—and laid a foundation for such men as Virchow, Cohnheim, Kuester, Rokitansky and others to

work out the microscopic anatomy after the middle of the century. During this period, the belief was ever increasing that the disease was infectious, but it remained for Villemin in 1866 to verify this by inoculating dogs with sputum. This paved the way for Koch's memorable discovery of the tubercle bacillus (1882). Ehrlich (1884) then showed how to stain Koch's bacillus so that it could be easily identified, giving us the acid fast stain. These three steps pointed the way for the profession to follow and revolutionized the social and public health aspects of the disease.

Following this Cornet, Flügge, Von Behring, and numerous others carried on experiments on the epidemiology of the disease. As previously cited, Von Behring also came to the support of a theory that has had an important bearing on our knowledge of the disease today, and forced us to realign our viewpoints.

The work on active immunity of tuberculosis has no doubt been the greatest stumbling block to research and more than anything else has put research in tuberculosis into disrepute by the poorly informed. Starting with Koch's old tuberculin, there have been hundreds of tuberculins, extracts, antigens, tuberculous proteins, defatted bacilli, polyvalent antigens, and similar preparations advocated. There have been others who have used or advocated living bacilli of attenuated virulence or otherwise. The most important and dependable work is that of Calmette (27) on cattle. He has undoubtedly applied to cattle in an experimental way what nature does during infection to man. That work cannot yet be applied to man; that is, to confer an immunity by repeated inoculations of accurate doses of living avirulent tubercle bacilli. There is hope in this field, and it may be worked out some time to a point of applicability and usefulness in human beings.

An important phase of artificial immunity is that produced in another animal and used in human disease. It would not be surprising to see great accomplishments along this line of work. It is especially encouraging since the Dicks have ferreted out the toxin of the streptococcus of scarlet fever, produced the antitoxin, purified, standardized both, and are actually preventing and arresting the disease. It is not unreasonable, therefore, to anticipate similar work in tuberculosis. In this field it seems that we have great hope for a therapeutic agent.

Starting with the work of Finsen on lupus vulgaris, light therapy has held an important place in tuberculosis treatment. It is quite possible that this is one reason why the primitive races have no tuberculosis because of the sterilizing and stimulating effect of the sun's rays. Amongst many others, Rollier (28) has achieved remarkable success with heliotherapy, not only in surgical tuberculosis but also in pulmonary tuberculosis, by putting his patients on a "primitive" regimen. Unquestionably there is some merit to it. LoGrasso (29) has reported excellent results from an "artificial sun's rays" also in pulmonary cases. The other lamps are only to be considered in superficial tuberculosis. There is undoubted possibilities in this field of work, but due to the difficulty of applying it and lack of heroic changes produced, it is questionable if this will be the method eventually found successful. It is true that all the rays have not yet been explored and some time a ray may be applied that will happily surprise everyone.

As with tuberculins, so with chemicals, drugs, etc., there have been hundreds of attempts with no results to date. There is no chemical or drug outside of food products that will modify the disease process *per se*. This field of work is difficult and few there are that find it or in fact hunt for it. However, there should be no delay in the attempt because should other efforts fail, *this is the field that we must fall back on for ultimate results.* And bear in mind tuberculosis is some day doomed to the lot of diphtheria, syphilis, and typhoid fever. As with these diseases, no results will be perfect, but the great sting will be removed and it is interesting to speculate how it will be removed, whether by immunological, chemical, prophylactic or sanitary measures. Already the prophylactic and sanitary measures based on facts established by laboratory research have made great inroads in the death rate of tuberculosis, but some time there must be a limit to this, and the laboratory must again come to the rescue. Furthermore a laboratory method for early diagnosis is needed and will surely be found. After all is said and done, there are great hosts of people who go to death without the least benefit from our present methods of treatment. There must be some treatment that will stop the progress of the disease when once established and shorten the convalescence. There must be something to save valuable men and women for society when they become stricken.

SUMMARY

As a résumé we may state that the natural means of defense against tuberculosis will become more potent in proportion to the frequency and extent of infections, yet, no more than it was a century ago, will it be sufficient to hold the disease in check.

By a combined effort on the part of the social organizations for the prevention of tuberculosis and public health bodies there will be a continued decrease in the death rate until its downward trend meets the upward rise of the effects of congestion and industrialization, when an equilibrium will result. To break this deadlock, some new measures originating in the laboratory must be evolved, either in the form of a method for early diagnosis, a vaccine, a serum, a chemical, or any two or more of these factors. Judging from results in other fields of work we may expect something within the next few decades that will at least remove the great sting from tuberculosis.

Indications for Suspension Laryngoscopy

R. H. T. MANN, M.D., F.A.C.S.
Texarkana, Arkansas-Texas

The simplicity and ease by which a direct examination of the larynx can be made I first saw demonstrated by Professor Killian, of Berlin, while attending the International Medical Congress in London during the summer of 1913. This method had just been introduced by him.

This procedure consists in holding the head in a

Fig. 1.—Position of the instrument being introduced into the mouth.

fixed position by the use of a suspension apparatus, attached to the side of any ordinary operating table, and holding the mouth open by a combined tongue depressor and mouth gag. The patient is placed on the table in the same position as for any ordinary throat operation.

The examination can be made with a local, general or no anesthesia, depending on the indications for each individual case. I prefer ether anesthesia, unless there is some contraindication. When the examination is being made, a warm ether vapor can be used to keep the patient asleep, as is done in an ordinary tonsillectomy, using the suction apparatus to keep the throat clear of mucus.

In small children where there is so much obstruction to breathing, the examination had best be made without any anesthetic. With the instrument closed, a suitable size tongue depressor having been selected, it can be introduced far enough down over the tongue to include the epiglottis; then, by raising the arm, the gag is placed against the upper teeth, the arm is now hung over the shaft, which is attached to the side of the table, and the larynx can now be brought into view by the manipulation of just three screws, one opens the mouth, the other elevates the tongue and epiglottis, while the third changes the position of the head by changing the angle of the arm.

It sometimes happens when introducing the tongue depressor one fails to get the epiglottis as well. Should this be the case, the instrument can be withdrawn and reintroduced, or the epiglottis can be held up with a long probe. When the tongue depressor is properly placed, it does not obstruct respiration.

Recently, an instrument, known as a directoscope, has been introduced by a Vienna surgeon. This instrument is not unlike a bivalve uterine speculum. One blade rests against the esophagus and vertebral column as a fixed point. By opening the blade, the larynx can be brought into view. The objection to this instrument seems to lie in the fact that it occupies too much space in the mouth and pharynx.

When the suspension laryngoscope has been properly placed, with any ordinary head mirror and

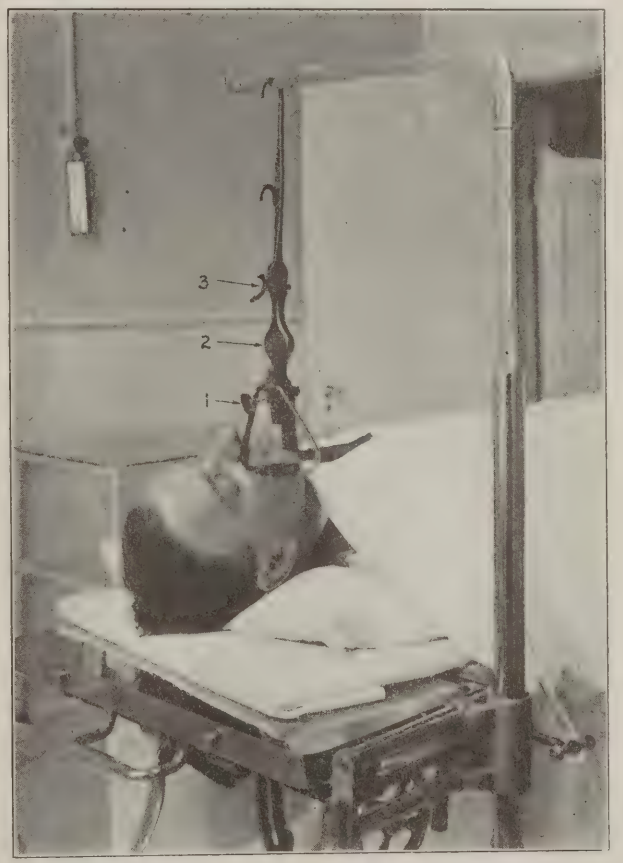

Fig. 2.—Position of the instrument in place. Screw No. 1 opens the mouth, No. 2 elevates the tongue and epiglottis, while No. 3 changes the angle of the arm, shifting the position of the head so that the larynx comes into direct view.

reflected light, the entire larynx can be inspected, treatments instituted, and operations performed by the use of straight instruments with as much ease as can operations be done upon the tonsil.

The bronchoscope can be introduced for examination, treatment and the removal of foreign bodies from the trachea and bronchi, without producing

trauma of the larynx as so often happens by other methods.

In the removal of foreign bodies from the trachea, should a first effort result in failure, the bronchoscope can be easily withdrawn and reintroduced. This method does not require trained assistants. The use of this method will prevent trauma of the larynx, which so often causes obstruction in children, necessitating a tracheotomy, or intubation.

In my hands, by this method, bronchoscopies, even on small children, can be easily performed as was formerly the case where a tracheotomy had been done.

When this method is put into more general use the removal of foreign bodies from the bronchi will be a much simpler procedure, and the necessity for a tracheotomy or intubation in these cases will correspondingly decrease.

The Clinical Interpretation of Pain

BENJAMIN LIPSHUTZ, M.D.,
Philadelphia

When a disease is accompanied by pain, this one symptom is likely to surpass all others in the patient's estimation. Among the symptoms which the physician is accustomed to deal with, pain is often the most baffling and misleading, so that we are sometimes tempted to belittle it and suspect our patients are guilty of exaggeration. Imagination may be its cause, Emerson remarks, but the pain thus produced hurts just as truly as pain produced by a real disease. Pain is a phenomenon of consciousness, and it is always real. Emerson adds, even that felt in a dream. Pain and discomfort as Head states are the oldest offensive reactions of the organism and potentially painful stimuli form the basis of most primitive reflexes. Pain is an adaptive function, which is present only where it is of value to give warning of noxious influences likely to injure the body unless removed. Even the simplest animal shuns pain and moves in the direction of pleasure.

Pain forms one of the most important diagnostic aids if properly interpreted. But in so many cases it is misunderstood, the intensity of the patient's suffering crying for relief, and attention is focused on relieving the pain rather than on its diagnostic sifinificance.

Few problems are more difficult and involved than those centring about the nerves of painful sensibility. The superficial parts of the body which are more directly exposed to traumatic injury are, in general, more sensitive to pain than are the deeper parts, and painful stimuli here can be more accurately localized. In some parts like the conjunctiva of the eyeball where slight irritation may seriously interfere with function, gentle stimulation gives rise to pain and no other sensory quality may be present.

Afferent impulses from the viscera do not normally enter consciousness. Some have tried to maintain that the viscera are insensitive and incapable of generating pain impulses, but no one who has observed a patient with renal or gallstone colic can look upon that statement as anything but hair splitting dialectics. Surgeons find that the brain membranes are sensitive to mechanical injury, especially to stretching and pulling. The brain substance itself, however, is quite insensitive to pain from either mechanical or chemical stimulation.

All the power of conscious response to heat, cold, pinching, cutting with a sharp instrument or other mechanical, chemical or thermal stimuli, is certainly absent from the deeper viscera of the thorax and abdomen. As Head puts it, internal viscera are unable to respond to such artificial stimuli to which they have never been exposed during the life of the individual or race. It must be recalled that receptors respond only when the stimulus is sufficiently strong and of the proper sort—degree of intensity and kind is, therefore, the adequate stimulus. Arthur Hertz has shown that a nerve ending may be sensitive to one form of stimulus—the adequate stimulus, but insensitive to all others. As long as the internal viscera are discharging their functions normally, the afferent impulses which they may originate do not enter consciousness. This is explained by suggesting that the cerebral cortex which is responsible for the discriminating functions of sensation, exercises a dominant influence over the lower centres, represented by the thalamus whose reactions are impulsive and urgent.

It is essential to recall that the majority of the cell bodies of the afferent or sensory sympathetic neurones are located in the ganglia on the dorsal roots of the spinal nerves and in homologous ganglia of certain cranial nerves. Cell bodies of a few afferent sympathetic neurones are apparently located in the extracentrally placed sympathetic ganglia. In spite of a certain peripheral autonomy in the physiological responses of the sympathetic nervous system, the latter is in large measure regulated and controlled by the cerebrospinal nervous system, a control made possible by the intimate anatomic connections of the two systems. This synapse relation in the dorsal ganglia between afferent sympathetic and afferent somatic neurons provides the mechanism for the transfer of sympathetic sensory impulses arising from the internal viscera to the somatic sensory system and thus enter realm of consciousness. By such anatomical arrangement the sympathetic sensory impulses from the abdominal viscera would be transferred from the sympathetic sensory system to the related somatic sensory system for sensory cortical stimulation; and since the function of sympathetic nerves in general do not come into consciousness, the transferred sympathetic sensory impulses may be referred by the brain as pain to the peripheral field of distribution of the associated somatic nerves and thus brought into consciousness.

Herrick's belief that collocations similar to those occurring in the spinal ganglia between the sympathetic and somatic sensory paths are undoubtedly established within the spinal cord and brain, probably offers the solution for referred pains in those regions where the necessary peripheral anatomical mechanisms for the transfer of sympathetic afferent impulses to the somatic afferent pathways are wanting or if they exist, are unkown.

CARDIAC PAIN

The heart muscle proper is quite insensitive to pain. The studies of Ziemssen in a patient with congenital fissure of the sternum and the experience of thoracic surgery confirm the fact that mechanical and other forms of irritation of the heart do not cause pain.

In contrast to the heart muscle the pericardium when inflamed is exceedingly painful. Pain is rarely absent as one of the symptoms of pericarditis. The pain usually manifests itself as a sharp or dull pain in the region of the apex of the heart, at times the entire pericardium is sensitive. In pericarditis it is frequently possible to elicit tenderness on pressure with the stethoscope, and on increasing the pressure with the stethoscope, the rub becomes more evident. The association of an increase of tenderness on pressure and the clearness with which friction rub becomes audible is often an equally definite diagnostic point in pleurisy. When the pleura is inflamed, the pain, stabbing in character, is intensified by every respiratory movement and becomes agonizing during a long deep inspiration which follows a cough, a laugh or a sneeze. It is absent when the side is at rest and is relieved by any treatment which immobilizes the chest, such as successful strapping. The pain as in pericarditis is frequently associated with tenderness on percussion in the intercostal spaces. Over this area of tenderness the pleuritic friction rub can usually be heard. The pain and tenderness appear to be definitely due to inflammation of the parietal pleura and possibly even to that which covers the lungs. Both disappear when the serous fluid is effused, but may persist over the upper border of pleural effusion in empyema.

As a rule pain is not a marked symptom of endocarditis. The occurrence of a cardiac pain during an attack of acute articular rheumatism, means not a pure endocarditis but an involvement of the endocardium, myocardium and the sensitive pericardium; a clinical syndrome frequently designated as carditis.

Diseases of the mediastinum and of the structures present in the various mediastinal spaces may be the cause of precardial pain. Inflamed tracheobronchial lymph nodes may produce cardiac pain. In two cases of carcinoma of the esophagus recently observed, the initial symptom complained of was precardial pain.

The stomach and the large intestines, particularly the splenic flexure, are two embarrassing anatomical neighbors of the heart, either of which when abnormally distended by its contents, either liquid or gas, may be the source of precardial pain and distress.

Concerning organic disease of the heart and its vessels, there are two lesions which are frequently prone to produce precardial pain. 1. Syphilis of the aorta, and 2, angina pectoris, thrombosis and embolism of the coronary arteries, and arteriosclerosis of the coronary arteries. The latter may be associated with aortic disease. Not uncommonly regurgitation or aortic insufficiency may cause pain over the precardium, whereas insufficiency of the other heart valves rarely induces pain.

DIAPHRAGMATIC PAIN

The localization of pain arising from the diaphragmatic pleura depends on the part of the diaphragm irritated. Clinical experience and observation during operation on and about the diaphragm under local anesthesia, show that only the peripheral portions of the diaphragm receive its afferent nerve supply from the lower sixth intercostal nerves. The pain may thus be referred to the abdomen, lumbar region or lower thorax, depending upon whether the sternal, costal or lumbar portions of the diaphragm are irritated. When the central portion of the diaphragmatic pleura is irritated, pain is experienced in the neck above the clavicles or in the neighborhood of the scapula. Irritation or stimulation of the central part of the diaphragmatic peritoneum is similarly referred to cervical segments, usually, however, to segments more caudal than is the case where the diaphragmatic pleura is affected. The explanation of the cervical localization of transferred pains from the central part of the diaphragm appears to have an embryological basis. For, notwithstanding the position of the diaphragm in the adult, it is a derivative of the cervical myotomes. Like the heart when first formed, it lies far forward in the uppermost part of the cervical region, but later descends with the heart until it reaches its adult position. The afferent cervical fibres being distributed to the diaphragm by the phrenic nerve, the belief that the phrenic and other socalled pure motor nerves are composed of but one type of fibres, needs to be revised. That the phrenic nerve contains afferent fibres has been established experimentally. In addition there is present in the literature a number of clinical studies which offer confirmatory evidence that afferent fibres are present in the phrenic nerve. Blocking of the phrenic nerve has been used successfully for the relief of shoulder pain in certain pulmonary infections, to induce immobility of the diaphragm during operation for diaphragmatic hernia and for the relief of intractable hiccough.

The occurrence of acute abdominal pain in thoracic disease not uncommonly clouds the clinical picture, adding great difficulty in establishing a definite diagnosis. As noted, inflammation of the pleura, or pericardium, syphilis or aneurysm of the aorta and arteriosclerosis of the coronary arteries may give origin to pain impulses that are transferred or referred along the intercostal nerves and produce acute abdominal pain. Less commonly, this referred abdominal pain may have its origin in mediastinal inflammation, caries of the thoracic vertebra, enlargement of the tracheobronchial lymph nodes or disease of the esophagus.

The anatomical and physiological basis of this referred pain is the following: The fact is recalled that early in the embryo the abdominal and thoracic sacs were one continuous, undivided chamber, the division occurring with the descent of the diaphragm. Furthermore, the thoracic and abdominal cavities

are both lined by serosa, the parietal portion of which is excessively sensitive. In addition, the oblique horizontal course of the intercostal nerves enables each nerve to supply afferent fibres to different parts of probably three segments of the body. Thus, neighboring segments of the thorax and abdomen, both surfaces of the diaphragm, may have a common source of afferent innervation. A further factor that complicates differentiation of the thorax and abdominal lesions is the synergistic action of the diaphragm and abdominal muscles. For any inflammation of the thorax or abdomen in which the parietal pleura or parietal peritoneum is involved induces definite interference and often complete loss of the abdominal type of respiration.

ABDOMINAL PAIN

For the clinical interpretation of abdominal pain, two types of pain should be differentiated. 1. Visceral pain, frequently designated as the socalled mesenteric pain, induced by pulling or tugging of the mesentery and by lesions not involving the peritoneal coat. 2. Peritoneal pain which results from irritation or inflammation of the highly sensitive parietal peritoneum. Frequently these types of pain are combined, but when present singly, they are characteristic and distinctive.

The abdominal viscera only rarely experience purely visceral sensations at the site of the lesion, but is usually localized higher in the abdomen. The latter is due to the fact that the majority of the sympathetic afferents arising from the abdominal viscera are centralized in the celiac plexus, from which site they are referred to the corresponding somatic afferent segment. It accounts similarly for the frequency of epigastric pain in lesions of the abdomen.

The only immediate cause of true visceral pain is tension; as far as the alimentary tract is concerned, this tension is exerted on the muscular coat. Experiments on the gallbladder and other abdominal hollow viscera show that the injection of even a small quantity of fluid so as to raise the pressure will cause disturbance due to the afferent impulses generated.

Visceral pain is usually felt deep in the abdomen and does not as a rule affect the abdominal wall. Occasionally, some deep tenderness may be present at the site of the subjective pain. As examples of visceral pain, may be cited the epigastric pain present during the nondestructive stage of appendicitis, i. e., before the involvement of the peritoneal coat; it is only with the involvement of the peritoneal coat that localized pain, tenderness and rigidity over the site of the appendix appear in the clinical picture. The epigastric pain present at the beginning or onset of a strangulated hernia and the epigastric distress in biliary and hepatic lesions.

Under the heading of visceral pain may be included the various colics, intestinal, biliary, renal and ureteral. Colics are characterized by 1, sudden onset; 2, sudden cessation, and 3, tendency to recurrence. In intestinal colic, the pain is referred above the umbilicus; the colic begins gradually, reaching its maximum point rather suddenly. The pain may reach a high grade, but never requires morphine for relief. The pain subsides suddenly. There now follows a longer or shorter interval of relief. This free pain interval is an important differentiation from peritoneal pain. The periodicity of the pain is dependent upon the excessive screwlike muscular contractions of the intestines.

The anatomical structure of the part involved is a factor of considerable importance in determining the character of the pain produced. In cases of ureteral and biliary colic, the powerful contractions of the musculature, the small lumen and the nonresisting fibrous coat, intensify the pain impulse as to make it unbearable and agonizing, so that only morphine gives relief.

Peritoneal pain in contrast with visceral pain is its exact localization at the site of the lesion. The pain is continuous and burning in character. There are no free pain intervals. It is naturally often combined with visceral pain. The pain of intestinal contraction is usually cutting in character. The intensity of the pain is not always alike, depending upon the cause and possible complications.

The intense acuteness of perforation pain and pancreatitis is the result of the continuous stimulation of both sympathetic ganglia and sensitive parietal peritoneum by chemical and toxic irritants.

Thomas has called attention to a pleural perforation pain which he regards as pathognomonic of the rupture of an encapsulated empyema into the pleural cavity. During convalescence the patient feels a sudden, sharp pain in the chest following slight exertion. In a few hours he becomes critically ill, there occurs an elevation of temperature to 102° to 104° F., the pulse becomes rapid and the respirations hollow and extremely painful. The pain localizes in the lower part of the chest or in the abdomen. Distention and marked tympany extending well up over the liver may be marked. The chest findings are not striking, but indicate the presence of a small amount of fluid. There is marked leucocytosis. Prostration is extreme.

As noted, pain may be evoked by either a noxious stimulus which attains a high enough grade of intensity to overcome the inhibition of the cortex or by disease or injury interfering with the paths through which the cortex normally exercises its control. But even when no such interference exists there is reason to believe that once the path has been opened and the dominance of higher centers overcome a weaker visceral stimulus will be followed by sensation, so that long continued irritation may give rise to pain from apparently inadequate causes. Certain bodily states may produce a diminution of automatic control, so that not only will a weaker stimulus cause painful sensations, but there may be a diffusion or spread of visceral pain and tenderness beyond the areas normally involved.

It is important to appreciate this possibility as it throws light on those puzzling cases in which the extent of pain and tenderness appear disproportionate to the existing cause. As example of this, Head mentions the conditions in which the stimulus is extremely severe as in gallstone or renal colic or a referred pain becomes chronic, so that not only is the resistance of the patient worn down by the disease, but the repetition of painful impulses facilitates their passages. Menstruation, anemia and debilitating general states such as worry or emotional shock may produce similar effects.

1007 Spruce Street.

Wassermann Control by Diet in Specific Types

WILLIAM E. KERNAN, M.D.
Boston, Mass.

I wish to report one of five cases of feeding the body in a cycle where laboratory data will show the relation of food to the body in disease. As in diabetes, the use of the heat foods by the body, principally starch, is of the most concern. It is only used as a unit of weight in the abdominal cavity, and so introduced causing visceroptosis, mostly at the third meal, and with no attention to caloric heat units. The other cases are much the same and on this same principle. Reactions are confirmed from more than one source.

As to the following diet cards, a close study of the heat factor, starch, will bring out its place in the daily cycle, the control and ability of the body to handle correctly just a certain amount, and the lack of control where too large a quantity is attempted. Where the reaction of October 16, 1923, clearly shows progress over the previous test of September 18, 1923, the large amount of heat food ingested shown by the diet slip of October 15, 1923, to November 11, 1923, gave us a return to "moderate positive" over the "doubtful" of the previous month. With the removal of the clear starch at the noon feeding and with a supporting dose of black coffee to support the abdominal load, and with hardly any change in the November and December 11th slips, we again obtain a "moderate positive" and with no progress, and bringing out clearly that we still could maintain a constant reaction. It was clearly up to the last two slips to show body tolerance and control in feeding in cycle and to bring out the principles of starch tolerance as governed by this unit of weight, alone, in the abdominal cavity. In two weeks, December 30, 1923, all heat food was removed at the noon feeding, carried through January and February, 1924, with negatives, to be called in after six months' absence to obtain another negative. No medication of any kind was used nor is being used in cases now in the process of cycling. The following data are presented in chronological order and dated, many slips at the start being written prior to the receipt of the reaction from the laboratory.

With such evidence I sincerely hope to stimulate interest in one way of feeding the body in disease and from a new angle where progress is only made in establishing body function of its own volition, a process both logical and rational, and where results are obtained without carrying an overburdened amount of laboratory evidence, as must exist in other forms of diets.

The patient, J. H. B., showed a positive Wassermann reaction on June 23, 1923.

JUNE 1, 1923

7. Black coffee at any time. Eggs if below 60° F.
12. Doughnuts or cake, water or black coffee if below 70° F. Milk to be raised to a quart if above.
6. Eggs and boiled onions, if below 60° F. with cake and black coffee, or if temp. is going to drop below 60° F. Asparagus on soft buttered toast, cake and black coffee if below 70° F. and above 60° F. Milk and crackers if above 70° F.
Add banana or graham bread only when milk and crackers are not enough and only when below 80° F. Crackers and milk and nonacid ice cream when above 80° F.
9. Milk if above 80° F. Cool bath before third meal.

Next visit June 15th.

JUNE 15, 1923.

7. Eggs, buttered toast at any meal, if between 60° F. and 50° F. always with black coffee. Black coffee always.
12. Doughnuts or cake, water and black coffee if below 70° F. Milk and crackers if above.
6. Asparagus on soft buttered toast, cake, water and black coffee if below 70° F. and above 60° F. Milk, banana, new potatoes and crackers if above 70° F. Milk and crackers and butter beans if above 80° F.
9. Milk and crackers if above 80° F. or nonacid ice cream.

Specific gravity 1004. Cool sponge or bath before third meal if above 70° F.

Next visit June 29th.

JULY 2, 1923.

7. Native fruit if below 70° F. and above 60° F. Black coffee.
12. Doughnuts or cake if below 70° F. Water and black coffee. Milk if above 70° F. and crackers. Eggs and buttered toast and boiled onions, cake, water and black coffee if below 60° F. Mackerel, tomato sauce, new peas, cake, water and black coffee if above 60° F. and below 70° F.
6. Milk, new potatoes, banana, crackers, if above 70° F. and below 80° F. Milk and crackers. Ice cream if above 80° F. Add new butter beans if above 80° F.
9. Milk if above 80° F.

Specific gravity 1006. Cool bath or sponge before breakfast if above 70° F.

Next visit July 16th.

JULY 23, 1923.

7. Eggs, buttered toast, if below 60° F. Water, black coffee.
12. Doughnuts or cake, water, black coffee if below 70° F. Milk and crackers if above.
6. Eggs and boiled onions, bread and butter, any kind of meat, all vegetables, milk below 70° F. Milk, potatoes, banana and bread if above 70° F. and below 80° F. Milk and beans and corn above 80° F. Ice cream.
9. Milk, if above 90° F.

Cool sponge before breakfast if above 70° F. or when hot during day.

Next visit August 13th.

AUGUST 14, 1923.

7. Eggs and buttered toast if below 60° F. and only if hungry. Water, black coffee.
12. Doughnuts or cake and water and black coffee if bowels do not move well at a. m. Milk and bread above 70° F. or milk and meat, etc., below 70° F.
6. Meat and milk and all vegetables if below 70° F. Milk and potatoes or banana or bread if above 70° F. and below 80° F. Milk and beans if above 80° F.

Cold sponge or bath if hot and only above 70° F.

Next visit September 11th.

On September 18, 1923, the Wassermann reaction was moderately positive.

SEPTEMBER 16, 1923.

7. Breakfast. Eggs and buttered toast. Water if below 60° F. Black coffee.
12. Milk and bread or milk and pie or milk and crackers if bowels move at a. m. Cake and coffee if not.
6. Milk and vegetables if below 70° F. Eggs added if above 50° F. and below 60° F. Milk and potatoes or milk and bread if above 70° F.

Soapy towel for cleaning. Cool sponge when hot and above 70° F. Next test October 15th. Next visit October 17th.

October 15, 1923.

The blood showed a doubtful Wassermann.

6:30 Breakfast. Oatmeal with milk and sugar if below 50° F. Eggs and buttered toast if above 50° F. and below 60° F. Black coffee always.

12. Bread and butter and one glass of milk if bowels move after breakfast. Cake and black coffee if they do not.

6. Bread and milk on any temp. Beans or chicken or frankforts if below 50° F. and above 40° F. Have lamb or corned beef dinner if below 40° F.

Specific gravity 1010. Quick lukewarm bath Friday or Saturday. Next visit November 14th. Next test November 11th.

On November 13, 1923, the blood showed a moderately positive Wassermann reaction.

November 14, 1923.

7. Oatmeal with milk and sugar if below 50° F. Black coffee.

12. Cake or doughnuts and black coffee.

6. Milk and bread on any temp. Beans, only when voiding gas and bowels have moved at a. m. and only when below 50° F. Chicken or frankforts only when tired of beans and on same conditions and only when below 50° F. and above 40° F. Add ham, lamb or boiled dinner to bread and milk on same conditions as to voiding gas and bowel motion and only below 40° F.

Specific gravity 1012. Lukewarm bath Friday or Saturday. Next visit December 12th. Next test December 10th.

On December 11, 1923, the blood showed a moderately positive Wassermann reaction.

December 13, 1923.

7. Oatmeal with milk and sugar if below 50° F. Water. Black coffee.

12. Cake or doughnuts, water, black coffee.

6. Milk and bread every night (milk to a quart) on any temp. Beans only when bowels have moved at a. m. and only when below 50° F. Chicken or frankforts, added to beans or alone, when tired of beans, but with milk and only when below 50° F. and above 40° F. Add ham, lamb or corned beef to beans or alone with milk on same conditions, but below 40° F.

Specific gravity 1008. Soapy towel for cleaning, no bath. Some water at 10, 2 and 8 p. m. Next visit December 30th.

December 30, 1923.

7:30. Breakfast. Grape fruit with sugar. Oatmeal with milk and sugar if below 50° F. Water, black coffee.

12. Black coffee.

6. Milk and bread or milk and bread and butter every night on any temp. (Milk to a quart.) Chicken or frankforts added to milk only if bowels move at a. m. and only if above 40° F. Ham or lamb on same conditions and only if above 30° F. and below 40° F.

Beef and turnip on same conditions and only if below 30° F.

Specific gravity 1012 a. m. specimen. Soapy towel for cleaning, no bath. Some water at 10, 2 and 8 p. m.

Next test January 18th. Next visit January 16th.

A negative Wassermann reaction was obtained on January 15, 1924, and February 12, 1924.

January 16, 1924.

7:30. Grape fruit, oatmeal with milk and sugar if below 50° F. Water, black coffee.

12. Black coffee.

6. Milk and bread or milk and bread and butter every night on any temp. (Milk to a quart.) Chicken or frankforts if bowels have moved and if above 40° F. Ham, lamb or corned beef on same conditions and if above 30° F. and below 40° F. Beef and turnip on same conditions and only if below 30° F. Raisins for dessert.

Specific gravity 1010. Soapy towel for cleaning, no bath. Some water at 10, 2 and 8 p. m.

Next visit February 13th. Next test February 11th.

February 14, 1924.

8. Breakfast. Grape fruit, oatmeal with milk and sugar if below 50° F. Water, black coffee.

12. Black coffee.

6. Milk to a quart and graham bread and butter on any temperature every night if bowels move at a. m. Beef if below 30° F. Other meats if above 30° F. Fried potatoes if below 40° F. if bowels have moved at a. m. Prunes or bread pudding for dessert. Black coffee if bowels have not moved in the morning.

Soapy towel for cleaning, no bath. Water at 10 a. m. and 2 and 8 p. m.

Next visit March 13th.

The Wassermann test made on September 5, 1924, was negative.

Rural School Medical Inspection

L. A. HULBERT, M.D.
Springville, N. Y.

Since August 1, 1913, when the State Medical Inspection law took effect providing for medical inspection of all children in public schools, outside of first class cities, there has been tremendous progress along this particular line of preventive medicine, especially in larger villages and cities. In rural districts, including villages of three thousand population or less, together with the surrounding territory, including school districts of six to twenty pupils, there is still present an appalling lack of proper organization of the work, and lack of efficient followup system. Yet here is to be found a great need for the exact education proposed by the state medical inspection law.

Few today question the importance of the school medical educational system, and its great opportunity for the physical and mental betterment of school children. The children of preschool and school age are the potential forces of our country today. And any system which tends to remove and correct any one or several of their physical or mental handicaps, or tends to establish and maintain a suitable environment for their full development, is of vast importance to the community, socially, financially, and economically. Robust, healthy children free from disease so far as humanly possible, with wholesome ideals built upon a groundwork of healthful habits developed in their early years, should be the goal of all school health work. The thing to be desired is not only the maximum health during school life, but its fruition in young men and women, who will have sound bodies, sound minds and a happy outlook upon life, which will enable them to contribute most to the future of the nation.

The essential to an effective plan for such health work in rural schools is proper organization, with leadership invested in the hands of a duly licensed physician, capable of making proper physical exam-

inations and mindful of the importance of slight defects, ever alert for minor deviations from the accepted normal, and familiar with hygiene and sanitation. There should be but one such medical inspector for a given section, appointed for a term of years, which will enable him to establish a system and remain in power to carry it to completion. It is the custom of some communities to appoint a medical school inspector, who is such in name only, and appointed solely for "getting by the law," the examinations being done by the family physician or whoever the child himself selects, the physician not seeing the child again for examination for several years if at all. Under such a system there can be no possible uniformity of results, or any standardization of methods. The result is that the child is examined from year to year by first one physician, then another, each stressing different points, reporting and rereporting defects, suggesting a wide variation of treatment, and succeeding only in collecting their fees, and greatly confusing the parents, and establishing an unfriendly feeling toward school medical inspection. Proper leadership and inspiration on the part of the community, together with an enthusiastic force of teachers with health ideals, and an appreciation of health measures, linked with an efficient followup system, would entirely do away with all this, and produce results entirely gratifying and well worth the money spent.

More than half of the school children of the United States are attending rural schools. And these children are on an average less healthy, and are handicapped more by defects, than are the children in the city. It is a mistaken idea that children reared in the open country, with its abundance of fresh air and sunshine, are healthier than their city neighbors. To be sure they should be, but, as a matter of fact country people have neither the knowledge nor the inclination to adapt these advantages to the healthful development of their children. By a comparison of available statistics on the prevailing defects among children in city and country it is found that teeth defects are fifteen per cent. more common in country children than in city children; diseased tonsils twenty-eight per cent. as compared with sixteen per cent. in city children; twenty-three per cent. of country children have adenoids against twelve per cent. in city children; eye defects are eight per cent. more common in the country; and sixteen per cent. of country children are malnourished as compared with seven per cent. of city children. It is evident, therefore, that the most vital phase of rural health relates to the health and welfare of the children.

The reason for the prevalence of such conditions is to be found, first, in the fact that the general impression among farmers is that if they live and conduct themselves as did their fathers and grandfathers before them they will be equally successful. As far as disease and health conditions are concerned, it is only a matter of heredity and environment. The existing conditions of the farm were good enough for their ancestors, and will also serve them. They had such and such diseases and so their children will probably have them also in spite of anything that is done. This conception is based on pure ignorance of the fundamental laws of health and disease, and a great lack of health interest and education.

Secondly, economic conditions are at the present time such as not to permit of the proper expenditure of time and money on preventive health measures. The farmer's time is entirely taken up with the problem of making a living for his family and maintaining his business interests. The demand from this source at times becomes so urgent that the older members of the family—both boys and girls—have to be pressed into long hours of service, sacrificing, consequently, health and education for the bare necessities of life.

It is not unusual to find boys of twelve and fourteen years of age getting up at three and four o'clock in the morning, the year round, going out and taking a man's place in doing the chores, coming in and eating a hasty unbalanced breakfast, and hurrying away to school, with only a cold lunch. Returning from school, they find more work waiting which requires several hours of their energy, getting to bed seldom before nine or ten o'clock with barely six hours to sleep when the same routine is to be repeated. There is always work on the farm and under presentday conditions of low prices, small crops, and shortage of dependable labor which can be had at a reasonable price, there is a tendency many times to keep the children at home to work and send an excuse to school for sickness. If this practice is not permitted, at the attainment of the age of sixteen years a working certificate is obtained. Thus the rural child is entirely cut off from his education and forced to live under conditions which prematurely age him and undermine his health.

Assuming there is proper education along health lines and time on the part of the individuals to permit them to carry out their instructions, there still remains a third factor which contributes very largely to existing rural health conditions. This is denial of proper medical attention, distance from clinics and dispensaries, absence of community health centres, and lack of proper school nursing facilities. This is a larger factor than at first supposed Many communities are entirely without medical services. Families have to depend on the services of a physician miles distant. Consequently minor conditions do not receive the proper care. Contagious diseases are not reported and quarantined. Small discomforts are allowed to pass. If the condition persists, a doctor is called in only as a last resort, and often only after serious complications have developed, which in many instances will permanently impair the individual, but are entirely avoidable if taken in time. Facilities are not at hand in the country for the proper examination, observation and study of health problems. The need for clinics is greatest in the field of prenatal medicine.

From a study of one school supervisory district situated in a western New York county, comprising five towns with a total of fifty-six districts, with a registration during 1923-24 of 1,886 pupils, it becomes very evident that rural health is being neglected, and that it offers great possibilities. These rural districts have an individual registration of from eight to six hundred and twenty-six pupils, with an average of 76.5 per cent. examined. Out of this number there were 1,385 defects reported, averaging about one defect to each pupil. Of this number of defects 1,297 were recommended for treatment and

only 27.5 per cent. of the recommendations or 25.7 per cent. of the defects were actually treated.

Teeth defects were the most prevalent. Tonsils and adenoids, and eyes followed next in importance. In nearly every instance all teeth defects were recommended for treatment, and it comprised also the largest percentage of treatments. It is to be remembered, however, that cases treated included all children who had their teeth cleaned, while defects included only actual cavities, deformities and diseased gums. Few cases of tonsils and adenoids were recommended for treatment. Of those recommended thirty-three per cent. were treated. The laity is coming to recognize the importance of diseased tonsils and adenoids, faster than are many rural physicians. The tendency is to dismiss the subject with the old and much abused saying: "They will outgrow them." Unless a tonsil exudes pus or is ragged and necrotic, it is seldom recommended for treatment. Mouth breathing, listlessness, physical and mental deficiency, loss of appetite and in many cases even facial deformity itself seldom suggest adenoids to the average rural physician examining in rural schools.

The eye shows a satisfactory percentage of treatment. Yet the type of treatment deserves some comment. The average defect is slight eyestrain; with vision 20/30 seldom less, occasional headache, and an effort on the part of the pupil to read. Burning and itching of the eyes, and blurring of vision are present in twenty to thirty per cent. of the children with defective eyes. When treatment is recommended for this type, the parents consider their duty complete when they have taken their children to an "eye doctor," who "fits them with glasses," which do not show the slightest degree of correction for myopia or astigmatism. In fact the probability of the existence of either of these defects did not enter the mind of the "eye doctor," his concern being simply to supply a pair of glasses.

In one school of over six hundred pupils ten per cent. of the girls showed evidence of goitre and only four per cent. were recommended for treatment and not a single one treated.

There is still another side to this study which in a measure may account for its very poor showing. Fourteen part time medical inspectors did the work, at a fee from seventy-five cents to one dollar a pupil. The actual time devoted to the work averaged eight minutes an examination, one school being done in the record time of six pupils in five minutes. The examinations constituted the inspector's entire part in the school health program. In those instances where notification cards were sent to the parents, it was taken care of by the teacher. No nurses were employed for followup work. Qualification of medical inspectors were not considered. Osteopaths did some examinations. Under this system $1,264 was spent for school inspection services; and on the basis of actual number treated only $303 value was received, the average yearly loss per capita being fifty cents.

It is no wonder that under such a system of school medical inspection that country children are less healthy and present more physical defects than those living in the city under a properly organized system. The results are not alone reflected in mental and physical health. The average group of farm children leave school before fifteen years of age, only twenty-six per cent. remaining in school until their sixteenth or seventeenth year. The grade completed is 7.7. Only forty-two per cent. completing the eighth grade. The rate of progress a grade a year is only 82.8 per cent.

Also it is notable and interesting that in this same group of children the great majority of those who are well along in school and accomplishing the best results, are the children who are physically fit and up to the average weight for their height. Children who are retarded in school grades are uniformly shorter and lighter for their years as well as underweight for height, while those who are in the proper grades for their age are the ones within the safety weight zone. From a study last year of 41,151 boys in Detroit, Michigan, there was found to be a close relation between underweight and backwardness in school, and between average and optimum weight and advance in school. Those from .7 per cent. to 8.5 per cent. underweight were retarded from one half year to four years in school. Those from 1.4 per cent. to 10.2 per cent. above average for height were accelerated from one half year to two and one half years in school.

It seems reasonable, therefore, to believe that if the great handicaps, defective teeth, diseased tonsils and adenoids, eye strain, and malnourishment were removed in the school child and prevented in the preschool child this average could be increased and consequently increase the efficiency of a very large group of our boys and girls.

RECOMMENDATIONS

The rural school medical situation at present is demanding attention, and with its natural facilities at hand it should be on a par with health conditions elsewhere. As a means toward this end, the following recommendations are suggested:

1. Less elastic State educational laws requiring the appointment of a school medical inspector and graduate nurse at a definitely stated salary, sufficient to carry responsibility with the position, whose duty would be to supervise a given area, determine the existing defects, direct correction and prevention.

2. State aid in the establishment of health centres or clinics, which can serve as a source of information and instruction, and to be used in conducting prenatal and preschool child work. Here also meetings could be held occasionally at which time vaccination, diphtheria prevention, etc., could be discussed. The health films of the State Health Department could be used to great advantage in this connection. These centres to be under the control of the school medical inspector and nurse.

3. Extensive encouragement of young physicians to locate in rural communities. This situation is becoming alarming. The general tendency is for graduates in medicine to stay in the city and specialize, to the extent that the general practitioner is gradually becoming extinct. At present they are relatively old men, and if this swing toward the city and specialization is not checked, a young man cannot be found in the country, and soon large areas will be entirely without a doctor. As a matter of fact it is not uncommon to find villages of from four to eight hundred population, with a large surrounding territory without a physician which only a few years ago amply supported one. Such conditions greatly hin-

der rapid progress toward organization of definite health programs.

Rural schools present many and varied medical problems. These must be met with a definitely organized system of inspection, education, and followup work, including health centres and clinics. Under the system at present working in many rural districts, the mental and physical health of nearly fifty per cent. of our school children is being neglected, besides being operated at a great financial loss each year to the district.

168 Main Street.

Artificial Pneumarthrosis as an Aid in Diagnosis

SAMUEL KLEINBERG, M.D., F.A.C.S.
New York

The usual clinical picture of a loose and injured semilunar cartilage is so definite that there is not much difficulty about its diagnosis. However, now and again, we encounter cases in which there is recurring or persistent effusion into the knee joint and disability, but there is no positive history of an injury or locking and the tenderness is not localized over the semilunar cartilages. In such instances, which are not at all infrequent, additional means of ascertaining the exact nature of the pathological change are desirable. Some time ago (1) I called attention to the value of injecting oxygen into joints before having them x rayed for purposes of diagnosis. I reported several cases in which this procedure helped to arrive at a positive diagnosis and indicated the proper treatment. In particular I gave an account of the case of a woman who, following an injury, had persistent pain and swelling of one knee. There had never been any locking. She walked with a limp and there was tenderness at the joint line, sometimes on the inner and sometimes on the outer side. The motions in the knee were painful, but only slightly restricted. There was evidently an internal derangement of the knee joint due probably, but not positively, to an injury of the semilunar cartilages. The usual x ray pictures were negative. The joint was injected with oxygen and another series of pictures taken. In the anteroposterior view two transverse linear shadows were visible, one above the external tuberosity and the other above the internal tuberosity of the tibia. These shadows presumably represented loosened and elevated semilunar cartilages, which would account for the symptoms. As the patient refused operation, I did not have the opportunity of verifying my diagnosis. Sir Robert Jones and Dr. Royal Whitman, to both of whom I described the case and showed the picture, agreed that the interpretation of the linear shadows was probably correct.

Recently a patient came under my care in whom I was able to confirm the diagnosis of loose internal semilunar cartilage made on the basis of a linear shadow above the internal tibial tuberosity shown in an anteroposterior radiogram of the knee after the joint had been inflated with oxygen.

Case.—Mrs. C. K., twenty-nine years old, applied for treatment at the New York Hospital for Ruptured and Crippled, October 13, 1922. She complained of discomfort and of something slipping in both knees; the right troubled her more than the left. She had had difficulty with the right knee for two years, but the left one became uncomfortable only three months previously. Dr. Whitman made a diagnosis of laxity of the right internal semilunar cartilage. He operated on the right knee on October 16, 1922, and removed the internal cartilage which he found to be entirely loose.

The patient consulted me on March 3, 1923, complaining of pain, swelling and stiffness in the left knee. She stated that her knee "locked" at times. From her description of locking, I doubted whether she appreciated what locking of a joint meant. She had never had any injury of the knee. The joint was enlarged and there evidently was a synovial effusion. There was tenderness on the inner side of the knee, but this was not definitely localized. While there was no doubt that there was an internal derangement of the knee necessitating an operation, and it was likely that the derangement was due to a loose semilunar cartilage, yet the diagnosis was not beyond question, as there are various conditions of the knee which might have given a similar clinical picture.

On March 6, 1923, after the usual surgical preparation, the left knee was distended with oxygen and x ray pictures were taken. The anteroposterior view showed a linear transverse shadow above the internal tuberosity of the tibia extending from the tibial spine somewhat more than half way across to the internal border of the articular surface of the tibia. There was a distinct interval between this shadow and that of the tibial tuberosity. There was no other discernible lesion. This shadow was interpreted as that of the internal semilunar cartilage which, being loose, had been lifted up from the tibia by the oxygen forced into the knee. A positive diagnosis of a loose and displaced internal cartilage was made and its removal advised. The patient was operated upon by me on June 1, 1923. The usual short vertical incision was made about an inch to the inner side of the patellar ligament. When the capsule of the knee was reached and before it was incised, the semilunar cartilage was palpable and found to be elevated from the tibia for at least a quarter of an inch. The capsule was incised and the anterior part or body of the cartilage was seen to be detached from its usual position. The cornua of the cartilage were in contact with the tibia. The cartilage was removed completely and the patient made an uneventful recovery, regaining complete and painless motion in the knee.

In an interesting paper on semilunar cartilage derangements read before the American Orthopedic Association in June, 1923, Dr. H. P. Mauck reported some experiments on injuries of the knees

in cadavers. By previously staining the cartilages he was able to show them in the radiograms. The case here reported is the first one in which I was able to demonstrate positively by radiogram before operation that the internal semilunar cartilage was loose and displaced from its attachment to the tibia.

The experience in this case is additional proof of

Fig. 1.—Mrs. C. K., anteroposterior radiogram of left knee. Note transverse linear shadow above the internal tuberosity of the tibia, indicating loose and elevated internal semilunar cartilage.

the value of the injection of oxygen into joints before x ray pictures are taken. By this method we are able to obtain shadows of the soft structures in the joints and can study their size, position and consistency. Thus we may obtain information that is helpful in the interpretation and understanding of the clinical phenomena. In a recent case I was able to prove by this procedure that the joint space in a tuberculous knee was completely obliterated by tuberculous tissue. This was important information because there was some motion in the knee and the patient's parents were especially anxious to obtain a cure with some function. With that in mind they denied their daughter the advantages of a timely excision of the joint. After the usual oxygen injection, I found the gas in the subcutaneous and periarticular tissues and none between the tibia, femur and patella. Having proved in this way that there was no joint space left, the parents were convinced and consented to the necessary operation. The correctness of the interpretation of the radiograms was then confirmed.

In the last few years the use of gas for distention of body cavities has been greatly extended and many interesting and valuable observations have been made. Stein and Stewart and latterly Rubin have done exceptionally good work and given us literally an insight into the abdominal cavity, which has at times revealed remarkably clearly, pathological conditions, which previously could be seen only in the operating room or on the postmortem table. Oxygen, nitrogen and other gases have been used and various more or less complicated apparatus devised. In the inflation of joints oxygen has served very well.

An ordinary oxygen tank is used; preferably one from which most of the gas has been removed so that the pressure is reduced and can be more easily regulated. A rubber tube two yards long with a lumen of a quarter of an inch and a stout needle about an inch and a half long complete all the equipment that is necessary. The needle and tube are sterilized. One end of the tube is attached to the tank and the needle is inserted into the other end. Some gas is allowed to pass through the tube and needle to clear the track of any fluid which may be there, and also to enable the operator to judge the degree of pressure in the tank. After painting the knee with iodine, the needle is placed on the outer side of the front of the knee just below and external to the patella. It is plunged into the knee in an upward, inward and slightly backward direction so that the point of the needle reaches somewhere behind the patella. The insertion of the needle can be executed so rapidly that in all but extremely neurotic individuals no local anesthetic is necessary. When the needle is in the joint it should be held firmly, otherwise the point of the needle will scratch the synovial membrane and cause discomfort. The gas is then allowed to flow in slowly; rapid distention of the joint is extremely painful. Under ordinary circumstances a joint may be distended sufficiently in about one to three minutes. The needle is withdrawn rapidly, a sterile dressing applied and the limb is ready to be x rayed. I have found no need for measuring the volume of gas injected. Enough oxygen is allowed to flow in to distend the joint so that there is a moderate swelling. Unless the joint is obliterated or the point of the needle is not in the joint cavity, there is little resistance to the flow of the gas.

Usually there is moderate discomfort, but rarely sharp pain, during the injection. This stops immediately or very soon after the needle is withdrawn. I have not yet had occasion to aspirate the oxygen because of severe or intolerable pain. The oxygen is gradually absorbed and disappears entirely in eighteen to seventy-two hours. Occasionally there is crackling in the skin for several days, but I have not seen any ill effects from the inflation of either joints or bursæ. Thus far I have made it a practice to keep the patient in bed for a few days, especially if the joints of the lower limbs were injected. This may be an unnecessary precaution but I have noticed that the patient himself is unwilling to move about much for a number of hours after the injection.

The inflation of joints and bursæ with oxygen has in many cases proved to be valuable. The shadows of pathological soft issue and of loose bodies are intensified because they are surrounded by the lighter areas of the gas, and hence are readily differentiated from the shadows of adjacent bones. I have by this method been able to demonstrate pedunculated and loose bodies, hypertrophied syno-

vial tissue, adhesion of bursal walls, obliteration of joint cavities, the size and extent of joint cavities and in the case here reported a loose internal semilunar cartilage, all of which conditions were not evident in the ordinary radiograms. The distention of joints with oxygen or artificial pneumarthrosis is a simple, harmless but important diagnostic aid which should be used extensively in the radiographic study of joints.

Common Duct Complications After Gallbladder Surgery*

JOHN W. WINSTON, M.D.
Norfolk, Virginia

My series of gallbladder operations are limited to a little over one hundred cases, and while I have learned something, they are not sufficient to interest you as much by themselves as they would if coupled with the experience of other surgeons and the literature of today.

Complications which follow gallbladder surgery may sometimes be caused by the operation itself and at other times they are not complications *per se* but the result of a preexisting pathological condition which was not removed by the operation.

The common bile duct and hepatic ducts are lined with tall epithelium in a single layer on a submucosa of firm elastic fibres that run longitudinally, and this is the main support of the tube that is capable of great distention. The epithelium undergoes quick repair and stretching of the elastic tissue is soon overcome unless there is a tear or cut in its continuity, with the production of fibrous tissue and stricture formation. Outside of the elastic tissue there is a muscular layer and a fibrous covering. In the duct wall are glands.

Judd calls postoperative lesions those that occur six months after operation, in order to be sure that in his series of cases they did follow operation, as those that exist before generally manifest themselves before that time.

Strictures along the duct, stones in the ducts, stricture at entrance into gut, adhesions, enlarged glands and tumor or malignancy of the head of the pancreas may all be preoperative, and while not the result of operation, should be looked for and not allowed to escape notice at operation. Cholecystitis and hepatitis may also be present before operation and may or may not be amenable to operation by draining, according to their cause, the length of time they existed and the extent of the damage already done. Damage to the common duct may be the direct result of the operation, such as traction on the cystic duct and tearing or breaking the common duct, partial or total cutting of duct, either longitudinally or crosswise, cutting cystic duct too flush or into common duct; traction of cut end of cystic duct may cause angulation.

All these may cause slight or great obstruction to the common duct sooner or later, from the resultant stricture. The cystic duct should be as accurately as possible identified and picked up clean, as blind grasping with forceps for the cystic artery may catch the common duct.

All gallbladders should be observed before resection is started and if the cystic duct can be identified, removal should be started from that end. If structures are covered with adhesions and separation is difficult, it is better to drain than to endanger the patient's life and risk future complications by persisting in trying to do a cholecystectomy.

I am not an advocate of removing the gallbladder by tackling a certain end always first, for in some instances they come out easier one way, and in other instances another way. When distended with stones or fluid it is sometimes safer to do a cholecystectomy after emptying the gallbladder. Before cutting the cystic duct and artery always fasten the ligature through the tissues around them, so that it cannot possibly slip. Do not trust the forceps to hold the ligature until you can tie it later, as all forceps will not hold and even if they do, it is not impossible accidentally to remove the wrong forceps or knock them off. Catching at a cystic stump is difficult to say the least, and if it falls against the common duct, may be caught with it.

After the cystic stump is securely tied, it should be allowed to take its own position and not be drawn tight by a continuous suture that closes all the raw area. Deaver says: "The nearer the patient is to being well when operated on, the surer he is of getting well." He further says: "The surgeon is never called too early but he may be called too late." He and all good surgeons recognize that there are cases of jaundice that do not need operation but what he means is that the longer operative cases stand before operation the less chance there is of complete and absolute recovery from the resultant damage done.

There are cases where cholecystectomy or cholecystotomy is done, when we have to take a chance as to the pathology that is left, but in all cases where possible, the common duct, the hepatic duct, the ampulla of Vater and the head of the pancreas should always be examined so that stones, strictures, tumor, enlarged glands and adhesions will be corrected. Adhesions of the gallbladder to the viscera should always be separated as fistula may be present.

The stump of the cystic duct may undergo dilatation, but it matters little if it does and should never be cut flush, as it may do more harm than good. Enough cystic duct to insure the integrity of the common duct is, in the opinion of the Mayos, the safest procedure and will rarely give rise to trouble.

Incisions in the common duct, whether for stone

*Read before the Norfolk County Medical Society, February 9, 1925.

or drainage, rarely cause trouble. The incision in the long axis of the tube is usually more useful, but the transverse incision is said to be no more prone to cause stricture. Infection of the gland within the wall of the duct is thought sometimes to cause stricture.

It is important at this point properly to interpret the history of the patient—pain, sharp and cutting, preceding jaundice. Painful jaundice is more amenable to permanent relief by operation than painless. Most operative pain from the obstructive type requires anodynes for relief. Pain and discomfort from gas accumulation, due to hepatic or bile insufficiency, are not so severe. Jaundice with or without leucocytosis has its significance. Chronic painless jaundice is a dangerous operative type and often malignant in either pancreas, ducts or liver.

We know that two mg. of bilirubin in one hundred c. c. blood is the normal amount and above that amount it becomes farther and farther away from normal. Blood chemistry goes farther and indicates whether bile in the blood is the obstructive or the hemolytic type. Sclerotic icterus and bile in urine rarely appear unless the blood content is above two mg. to one hundred c. c. Deaver wonders whether the quality of the bile in the tissue is not as important as the quantity and what future investigations may assign to quality.

Mayo says that biliary cirrhosis is most often the result of infections and obstructive processes having their origin in the gallbladder or common duct, usually from gallstones.

Personally, I believe that all gallbladders that are distended at all, that do not empty readily and easily, and that have a history of nausea and gas accumulation, should all be taken out in abdominal operations, where no more than trivial additional dangers are incurred. The gallbladder as a rule is not as sudden an enemy as the appendix, but in the long run it claims more victims than its rival and the day may come when we shall not say that an innocent gallbladder has been removed, as is not said of an appendix.

In the biliary cirrhotic type where the liver is enlarged, dark in color, bleeds easily and is soft, the infection must be eradicated by the removal of all stones whether in the ducts or the bladder; removal of the infected gallbladders and in addition drainage of the common duct by the T-tube of Kehr or catheter as used by Robson.

In chronic types where the liver is enlarged, lighter in color and hard and the ducts are thickened and the spleen enlarged, removal of the spleen and prolonged drainage are indicated. Some light may be obtained from the fact that paroxysms of acute pain due to stone obstruction can only be relieved medically by morphine, while pain due to muscular contraction, though intense, is easily relieved by intravenous injections of atropine alone, which is said to produce no bad effects except flushing of the face and dryness of the throat.

Jaundice and sudden clay colored stools accompanied by colicky pains which are not relieved by atropine alone but require morphine also, indicate stone within the bile ducts. Catarrhal jaundice in young persons free from clay colored stools, not painful and not obstructive, is not operative.

A kink in the cystic duct may cause great distention and discomfort, as will often obstructions of the cystic duct from stone and inflammation, and requires only the removal of the gallbladder and duct beyond the point of obstruction.

In jaundice of cholangitis, not due to stone obstruction of the common duct, but to choledochitis with thickened duct walls and normal gallbladder, anastomosis of the gallbladder to the second portion of the duodenum is indicated. If the common duct is obstructed by stricture this operation may suffice, but dilatation of the stricture with T tube drainage is perhaps better. Whether fresh or old, where the tube is severed it should be joined end to end and drainage inserted, but if the distal end is destroyed and cannot be dug out, a tube from the proximal end into the bowel will sometimes establish a canal from the continuous flow of bile.

Where possible, the hepatic or common duct should be linked with the bowel and no attempt made to form a duct from tissues, as it does not act well. Even where everything is covered with adhesions and the foramen of Winslow is occluded, do a painstaking dissection and get the best exposure possible, for again in the words of Deaver, "to operate blindly is to operate unsuccessfully." And again, Deaver says, "Faith in negative x ray findings and medical drainage are in part responsible for delayed operation and to no less degree for failure to make an early diagnosis."

Chloride of calcium intravenously may be of value in preventing hepatic insufficiency and postoperative bleeding. Bilirubin may rise from the normal two mg. in one hundred c. c. blood to eight mg. in one hundred c. c. blood without visible jaundice after obstruction to the flow of bile. Visible icterus in the skin, urine or scleræ depends more on the duration than the amount. Blood chemistry then is quicker to detect jaundice than is visible icterus.

The usual site of the stricture in the common duct is at the junction of the cystic duct, as the most common site of injury is the least dilatable portion of the duct and the most frequent location of inflammation. A fistulous opening leads to stricture, as the end of least resistance generally stays open.

The youngest patient I have operated upon was thirteen years old and the oldest ninety-two years old. I have had four deaths which is less than four per cent. This is partly luck and partly due to the fact that in many cases the gallbladders were removed at other operations where disease did not extend beyond the gallbladder.

Two of my patients were operated upon the second time by me, one a month after the first operation for continued purulent discharge, when a piece of gauze was removed, followed by rapid recovery.

Another patient who was greatly jaundiced was operated upon by me three years after cholecystectomy. In this case three glands the size of the end of the thumb were removed from around duct. These glands were causing pressure, and drainage was put in, with recovery after long drain.

Another patient complained of intermittent colicky pains without jaundice, but refused another operation. The patient later died from a fall and at postmortem a stone was found at the papilla of Vater. This stone had been overlooked at operation.

The Combined Right Inguinal Hernia and Appendix Operation

By HARRY COHEN, M.D.,
New York.

In the past few years, frequent clinical reports of cases of acute appendicitis encountered in inguinal hernias have appeared in literature. Wildman (1) reports such a case that came under his observation and reviews the literature citing very many more. Another class of cases that are not reported are those of appendicitis in patients who have previously undergone right inguinal hernia operations. Many such cases have come under my observation, as they have to almost all surgeons, and a review of these would be superfluous.

In an article over a year ago (2), I demonstrated the simplicity of doing the combined operation where the inguinal hernia was on the right side. In that article the anatomical relationship between the appendix and the right internal ring was demonstrated. With this operation as a routine, many of these subsequent appendectomies would have been avoided. There are other and more potent reasons for doing the combined operation. In the majority of the appendices so removed, distinct gross pathological changes were found. Only a small proportion are macroscopically normal. The majority are of the chronic adhesive type and not a few are subacute or even acute.

In children the cecum is freely movable and may at times be found anywhere in the abdomen; consequently the appendix in these patients has a greater range of mobility than in adults. Only in adolescence does the cecum become fixed to the posterior abdominal wall. In a considerable number of cases, the cecum and occasionally the ileum is found adherent to the sac. These adhesions may at times be very firm and numerous. In such cases the appendix is frequently caught in these adhesions and a simple herniotomy would leave chronic appendicitis and adhesions with their concomitant symptoms of pain and intestinal disturbance. There are many reasons for these adhesions, among which are the continual irritations produced by the hernial contents passing through the inguinal canal. Productive inflammation is caused by trauma, especially by the pressure of a truss. The presence of these adhesions is another indication for exploring the region of the cecum and incidentally of removing the appendix. This is a harmless procedure if it is normal and an indicated one if it is found to be chronically inflamed and bound down with adhesions. There is no danger in the removal of the appendix through the hernial sac, no delay or appreciable prolongation of time and no complications. Recovery should be uneventful. Some difficulty may be encountered in locating and bringing down the appendix through the sac, but with a little practice this difficulty is overcome. Where any is met with, a recourse to the fixed landmarks will be of service. These are the brim of the pelvis and the attachment of the mesentery. Sweep fingers downward along the outer wall of the abdomen about one inch above the brim, and feel the attachment of the mesentery and the appendix. With a little gentle traction, aided either by a ring clamp or a piece of gauze, the cecum is mobilized in the wound, and with it the appendix, the removal of which is accomplished without difficulty. This routine removal of the appendix through the hernial wound stood me in good stead in one case where I found an acute appendicitis.

REPORT OF CASES.

CASE I.—M. K., aged thirty, was admitted to the People's Hospital in February, 1916. The combined operation was performed and the appendix found to be normal.

CASE II.—S. G., aged eight months, was admitted to the People's Hospital on February 26, 1916, for a strangulated right inguinal hernia. On releasing the constriction about the ring, the appendix was found in the sac and was red and inflamed. The appendix was removed and herniotomy performed. The patient made an uneventful recovery.

CASE III.—S. W., aged forty, was admitted to the People's Hospital, May 7, 1916, for a strangulated right inguinal hernia complicated by a teratoma of the testicle. The combined operation was performed and the appendix found to be normal.

CASE IV.—S. F., aged twenty-two, was admitted to the People's Hospital, October 3, 1916. In this case an acute appendicitis was found in the sac. The pain was located entirely in the large hernia. Recovery was uneventful.

CASE V.—J. G., aged thirty, was admitted to the Flower Hospital, October 21, 1916, for a double inguinal hernia. This patient had been suffering from chronic appendicitis for many years and had been advised to have his appendix removed. The combined operation was performed. The appendix was bound down by adhesions and on removal the lumen barely admitted a probe. Recovery was uneventful.

CASE VI.—W. K., aged one year, was admitted to the People's Hospital, January 17, 1917, for an incarcerated right inguinal hernia. In this case the appendix was found in the sac. Combined operation was performed; recovery was uneventful.

CASE VII.—F. W., aged thirty-seven, was admitted to the People's Hospital, March 14, 1917, for a right inguinal hernia complicated by an undescended testicle. The combined operation was performed. Appendix was normal.

CASE VIII.—A. W., aged eight, was admitted to the People's Hospital, April 15, 1917, for a double inguinal hernia. Combined operation was performed. The appendix showed acute catarrhal inflammation.

To conclude, the operation is simple and many of the appendices removed will be found to be pathological. There is no added danger in the operation, no undue prolongation of time in performing it, and the stay in the hospital is no longer.

Practical Therapeutics

THE NEW SPECIFIC THERAPY IN COLLAPSE*

KURT PETERS, M.D.
Woodside, New York

Favorable reports are continually appearing regarding the specific method of treating collapse through stimulation of the respiratory centre with the alkaloid alpha-lobelin.

For the general emergency service, such as that of first aid stations, ambulances, police and fire stations, mines, gas and electrical works and other industries, this new method is of prime importance as it is also for every physician.

The method has been tried and evaluated under such varying conditions as poisoning by narcotics, diphtheritic collapse, asphyxia neonatorum and imprisoned miners. It therefore seemed desirable to subject the clinical reports to critical selective analysis in order to determine and sharply define the syndrome indicating respiratory stimulation.

Based upon the pharmacological findings of exhaustive tests alpha-lobelin is clearly indicated in all forms of central respiratory depression, either partial or complete.

The preparation directly stimulates the respiratory centre causing respiratory movements, an increase in volume and a vigorous interchange of gases. It becomes effective immediately upon injection and continues so for from a half hour to an hour and a half. It can be repeated as frequently as desired, or its effect made continuous by prolonged infusion without danger of cumulative effect.

The accompanying respiratory curve of the pharmacologists Behrens and Pulewka shows the results of one of the twelve resuscitation experiments on cats.

After respiration had in some cases been partially and in others wholly stopped by a mixture of carbon monoxide with air, fresh air was introduced. Respiration did not improve and death seemed inevitable. Intravenous injection of 0.002 gram of alpha-lobelin immediately produced both increased frequency and amplitude of respiration and saved life in all twelve cases.

The application of alpha-lobelin is thus indicated in all conditions of apnea or oligopnea but not in dyspnea, for here the centre is already reacting to its physiological stimulus, carbon dioxide, and in turn acting forcibly upon the respiratory musculature. Apnea and oligopnea are the symptoms of respiratory depression encountered in the various special fields of medicine under different names.

In order to give the physician the right orientation for using alpha-lobelin we have endeavored to arrange the different forms of central respiratory depression into an etiological system.

In the conditions called collapse and shock the primary phenomenon is usually central respiratory depression with venosity of the blood; the cardiac depression appearing only secondarily as a consequence of venosity of the coronary circulation.

*Read before the New York Academy of Medicine.

The causes of partial or complete respiratory depression may be either psychic, as in fainting from fright; physical, as in electric shock and hemorrhage; or chemical.

Among the chemical causes, paralyses of the respiratory centre by poisoning play the most important rôle. Through the blood stream the respiratory centre is bathed with exogenous poisons, such as ether, chloroform, morphine, carbon monoxide gas (illuminating gas, stove gas, automobile and mine fumes)

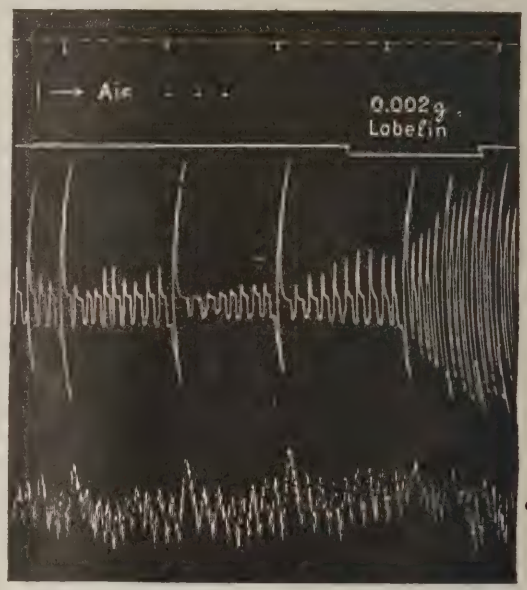

FIG. 1.—Respiratory curve. *a*, time thirty seconds; *b*, respiration; *c*, blood pressure.

and smoke, or by endogenous poisons, such as too high concentration of carbon dioxide or other catabolic products of metabolism (acidosis), the oxidation and elimination of which are disturbed.

Respiratory depression by endogenous poisons, recognizable by cyanosis, may appear in the course of almost every disease and may lead to complete collapse. This form appears physiologically in death. The most frequently observed forms of this group are asphyxia neonatorum, drowning and surgical shock.

All these forms of central respiratory depression are indications for the stimulation of the respiratory centre by alpha-lobelin. Artificial respiration sometimes requires as long as eight hours to produce the results given by alpha-lobelin in minutes.

The marked convenience of the ampule is in sharp contrast to the cumbersome equipment required for artificial lung ventilation or inhalation of oxygen.

The irrational treatment of emergency cases with a cardiac stimulant need no longer be practised with this specific respiratory stimulant at hand.

THERAPEUTIC NOTES

Charles Greene Cumston, M.D.
Geneva, Switzerland

UNTOWARD EFFECTS OF TARTRATE OF BORAX AND POTASSIUM

It would appear that the tartrate of borax and potassium is not always devoid of untoward effects, as is generally assumed. Recently Professor Ide stated at a meeting of the Royal Academy of Medicine at Brussels, that borax medication might give rise to relaxation of the bladder.

One of his cases, which is well worth relating as it is almost equivalent to a laboratory experiment, was that of a male, aged nineteen years, who from infancy presented a strange phenomenon. Every time a sudden unexpected sound occurred, such as the slamming of a door, the patient would manifest a tetanic shock similar to one developing in a strychninized frog when the table on which the animal is lying is struck with the finger. The limbs on the right were more particularly thrown into a short tetanic paroxysm, but the entire body also was involved in the shock. There was no loss of consciousness during the attack and in less than a minute the patient had regained control of his muscles.

As to treatment, Professor Ide first gave bromide for a number of years, and later combined it with luminal; two grams of bromide and ten centigrams of luminal twice daily produced a relative amelioration of this abnormal irritability. Now, in order to mitigate an annoying furunculosis, Ide reduced the bromide to one gram daily and the luminal to five centigrams daily, and at the same time ordered three grams of tartrate of borax and potassium in twenty-four hours. During the first week of this medication, an entirely new phenomenon developed; at each paroxysm, the patient emptied his bladder in his clothes. This was the cause of great distress to the patient, who reduced his intake of fluids and urinated as often as possible, but regardless of this, he would wet his clothes several times a day. The tartrate was stopped and micturition became normal.

A month later the patient again took one gram of the tartrate, and again he urinated involuntarily, but when the drug was permanently given up, there was no return of the bladder disturbance.

HYPERTONIC SOLUTION OF SODIUM CHLORIDE IN GLAUCOMA

From considerable experience, Dr. L. Weekers, of Liège, has found that intravenous injections of a hypertonic solution of sodium chloride exercises a favorable action on the ocular hypertension in acute glaucoma. Weekers follows Cushing's method employed in cerebral hypertension, consisting of an intravenous injection of a sterilized watery solution of sodium chloride at thirty per cent., the average dose being five c. c. When given slowly at the rate of one c. c. a minute, no untoward effects occur. Occasionally, nervous subjects experience a slight malaise with some sweating, and in order to obviate these trifling disturbances, it is better to give the injection with the patient lying down.

One or several injections, given at intervals of one or two days, will be enough notably to decrease the ocular hypertension. But this effect is fleeting, lasting only a day or two, and even when repeated, the injections by themselves will be found insufficient to maintain the effect first produced, the ocular tension soon reaching the same degree as before treatment.

Nevertheless, Weekers recommends these injections as valuable for "normalizing" an eye which is the seat of acute glaucoma, before doing an iridectomy. In hemorrhagic and absolute glaucoma, the hypotensive effect of the injection usually is not very manifest. In chronic glaucoma and secondary glaucoma, the effect is nil or extremely slight.

TREATMENT OF GASTRIC ULCER

The part played by the enervation of the filaments of the vagus nerve in the surgical treatment of gastric ulcer has been carefully studied by Dr. Gianolla, surgeon in the Belgian army. He found that the nerves of the stomach form a system and that each one of them maintains an autonomous course in contact with the stomach and plays an independent part and a perfectly limited area of action.

There are three distinct bundles, the most important being at the lesser curvature, its branches being derived almost entirely from the pneumogastric. This bundle comprises an anterior and posterior branch derived from the corresponding pneumogastric nerve. The gastric area controlled by these two branches is the median portion of the stomach, otherwise put, the evacuating portion of the organ, the pylorus excepted. The nerve bundle supplying the greater curvature is derived from the coelic plexus, while the third bundle, or subpyloric

branch, comes from the hepatic quadrant. From the physiological viewpoint, total or partial enervation automatically produces vasodilatation in the corresponding area of the stomach, and this only in the parietal layer. This vasodilatation is accompanied by hypotonicity, a delay in the evacuation of the gastric contents, and decrease in amount of secretion.

Clinically, the indications for enervation comprise at the present writing, three pathological conditions, namely, 1, the lightning pains of locomotor ataxia; 2, in gastric ulcer combined with the usual surgical procedures, and 3, in gastropathies of the vagosympathetic type. Hence, gastric enervation is indicated in all cases of painful hypertonic gastric processes with hypersecretion.

Since we are speaking of gastric nerve surgery, I cannot refrain from referring to the work done by Dr. G. Lemoine, of Brussels, on the surgery of the sympathetic nerve, and especially of the gastric vagosympathetic. He has shown that the true sympathetic system controls the functions of vegetative life, hence governing the excitomotor function of the sudoriparous glands, the pilomotor and vasomotor apparatus, as well as a number of sphincters of the digestive tract, and presides over certain acts of inhibition of the musculature of this tract.

The vagus and pelvic nerve each participate in the innervation of the digestive system, and its embryological derivatives, namely, the bladder and respiratory system.

The respective actions of the vagus and sympathetic nerves on the motility of the stomach and gastric secretions is still a moot subject. Irritation of the vagus and splanchnic nerves may either produce a motor or inhibitory action, everything depending upon the state of tonicity of the peripheral mechanism. The local visceral nerve supply suffices for the local organic functions, but the extrinsic vagosympathetic system controls and adapts the functions in the event of possible disturbances of the normal physiology of the stomach.

The results of Lemoine's experimental work has led him to conclude that surgical intervention of the nervous system of the stomach is indicated in the gastric crises of tabes, gastric ulcer, and in the painful vagosympathetic syndromes. The operation consists either of elongation of the solar plexus and excision of the semilunar ganglia or partial or total enervation of the stomach and not infrequently the operative results are encouraging.

Treatment of Enteric Fever.—F. H. Thompson (*Clinical Journal,* July 2, 1924) says that the sooner the patient is in bed and kept in the recumbent position the better, for in a disease so prolonged and exhausting it is essential to conserve every ounce of his strength. Therefore the mere suspicion of this disease should cause the patient to be sent to bed at once, and he should not be allowed out of the recumbent position for any purpose whatever. The room should be large and airy, quiet, well ventilated, but free from draughts, situated where in winter the maximum sunlight is available and in summer shaded from its blaze. The temperature of the room should be about 60° F. The bed should be of the hospital pattern, three feet wide with a firm hair mattress, and so placed that it is readily accessible on bot sides. It should not face the window. Traine nurses should be engaged for day and night with, i possible, experience in enteric fever nursing. A rul ber sheet should always be under the patient with draw sheet above it. The draw sheet must be draw tight and have no creases; further, it must be kep dry and clean in order to avoid irritating the patient skin in any way, else bedsores may occur. Th patient must never be left alone. Every patien should be blanket bathed night and morning, and in addition, frequent tepid sponging is necessary i severe cases, carefully drying the part sponged be fore uncovering the next area of skin to be deal with. Bedsores should never occur, but great pre cautions are necessary to insure this. All parts ex posed to pressure must, after the morning and eve ning blanket bath, be rubbed with methylated spiri and dusted with powder, but it must be seen tha there is no caking of the powder. Further, the posi tion of the patient must be frequently changed fron the back, first to one side, then to another. He ca be kept in the desired position by pillows. In sever cases a water or air bed may be necessary. Afte each motion the skin of the buttocks and thighs mus be carefully sponged, dried and powdered. An out look should be kept for retention of urine. Th mouth must receive careful and frequent attention being cleansed every three or four hours with a weal solution of boric acid, then moistened with glycerin or borax, not forgetting the lips, and finally a dro or two of fresh lemon juice should be placed on th dorsum of the tongue. The teeth should also b brushed twice or thrice daily.

The patient must be given plenty of water t drink, and milk must not be used for quenchin thirst, but as an article of diet only. Various authori ties give widely differing opinions as to the prope diet for the enteric fever patient, but the point t bear in mind is that in so far as possible his strengt must be maintained, and that consequently the die must vary within limits according to the severity o the attack, the powers of digestion, and the persona peculiarities. Large quantities of food may sui some but do harm to others. It is necessary for th physician to study each case and avoid a routine diet Speaking generally, milk is the best food. It shoul be given at regular intervals and in stated quanti ties, though sleep must not be interfered with un duly. The patient should be fed about every tw hours, but at night if he is sleeping the interva may be prolonged to four hours, so long as in twenty four hours he takes three pints (if a child, two pints in feedings of about equal quantity.

Thyroidin Treatment of the Nephroses.—Do menico Campanacci (*Wiener klinische Wochen schrift,* March 13, 1924) used thyroidin treatmen in three patients, aged three, eighteen and forty eight, respectively, suffering from nephritis with dropsy but without retention of nitrogen, all three of whom recovered. The dose advocated by Eppin ger, namely, beginning with 0.3 gram of the dry sub stance daily and increasing it gradually up to 1.2 to 1.8 gram daily and even more, was followed. This treatment requires great care of application and constant medical observation.

Symposium on Gynecology and Obstetrics

NEW YORK, WEDNESDAY, MARCH 18, 1925

Present Day Management of Uncomplicated Labor*

J. P. GREENHILL, M.D.

Chicago

It is an undisputed fact that a large number of women lose their lives every year as the direct result of childbirth; and of those who do not lose their lives, about one half suffer for years from the effects of labor. Approximately one half of our gynecological operations are necessitated by the damage resulting from labor. Aside from the maternal mortality and morbidity, there is a large fetal death rate. According to De Lee, in the United States alone about twenty thousand mothers and over one hundred thousand babies lose their lives every year as the result of childbirth. These figures are frightful; but fortunately most of these deaths and injuries are preventable. Careful observation of patients during pregnancy and the proper conduct of labor will considerably reduce both maternal and fetal mortality and morbidity.

Prophylaxis is most essential in pregnancy and for its success education of the public is necessary. The layman must be made to realize that a labor case begins at the time of conception and that it is important for the pregnant woman to see a physician as soon as she knows she is pregnant. Once the patient is in the hands of a physician, the responsibility rests largely upon him. He must properly instruct the patient and guide her through pregnancy so that she and her child can go through the ordeal of labor with a minimum of injury.

Since a labor case begins at the time of conception, it is within the scope of this paper to discuss prenatal care briefly. At the patient's first visit there are certain fundamental things a physician should do. First of all it is essential that a history along certain lines be taken. It may help to know the childbirth experiences of the patient's mother and sisters and the patient's past illnesses and operations. If the patient is a multipara, her past obstetrical history is important because as a rule a woman shows her obstetrical form in her first labor. After taking the history, the patient should be given a careful general examination which should include not only the heart and lungs but also possible sources of infection such as the teeth, tonsils, sinuses, etc. Of great importance is the special obstetrical examination which consists of external and internal measurements, abdominal and vaginal examinations.

The patient should be seen by the physician at least every three weeks during the first seven months of pregnancy and every two weeks thereafter. During these visits the blood pressure should be taken, the urine examined and the general health of the patient observed. From time to time an abdominal examination should be made and the fetal heart auscultated.

At the first visit certain information should be given the patient, preferably in typewritten or printed form. The patient should be told to regulate her diet so as to eliminate as much meat, fish and other proteins as is convenient She should drink an abundance of water and see that her bowels move daily. A certain amount of light, outdoor exercise, usually walking, is essential. Circular constrictions, especially circular garters, should be forbidden. Sexual intercourse should be restricted during pregnancy and absolutely forbidden during the last six weeks. The physician should be notified if any of the following symptoms arise: edema, severe headaches, visual disturbances, diminished urinary output, bleeding, excessive vomiting, marked constipation or epigastric pain.

When a woman goes into labor the best place for the delivery is a hospital; but unfortunately the majority of women are still delivered in their homes. Of prime importance for the physician who delivers his patients at home, is preparedness, not only in knowledge but also with instruments. If possible, an assistant, a physician or nurse should be present.

When called to a patient in labor it is advisable to respond as quickly as possible. A careful abdominal examination should be made to determine the exact presentation and position of the child and the fetal heart tones should be counted. The amount of effacement and dilatation of the cervix should be determined, preferably by rectal examination. With a little experience one is able to conduct fully ninety-five per cent. of all labors without vaginal examinations. The blood pressure should be measured and the urine examined because a sudden

*Read before the Lee County Medical Society, Illinois, January 3, 1925.

change may have taken place. If the heart and lungs have not been examined before, they should be at this time.

The general plan of treatment in the first stage of labor is one of watchful expectancy. This consists of lessening the strain of labor by morphine and scopolamine, or morphine and atropine, seeing that the bladder and rectum are kept empty and that

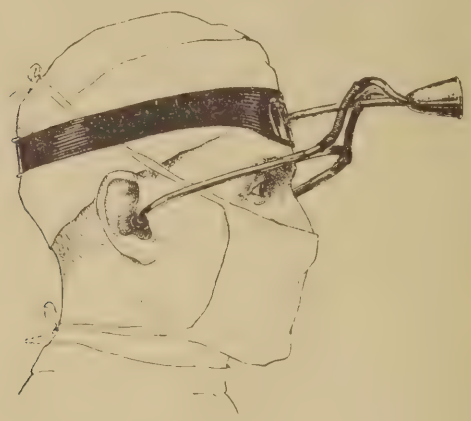

FIG. 1.—The De Lee-Hillis stethoscope.

the patient takes nourishment. Careful observation of the fetal heart tones is important. The patient should not be permitted to bear down during the first stage as it is useless and will waste her strength which will be necessary for the second stage. Furthermore, expulsive efforts may do harm by forcing the undilated cervix downward and prepare the way for a future prolapse of the uterus.

Throughout labor one must watch for signs of trouble. Nature usually throws out little signals, which if properly evaluated, give us a clue that something is wrong. If there is evident disproportion between the child's head and the pelvis (and hydroecphalus can be excluded), Cæsarean section is of course indicated. If uncertain about disproportion, the patient should be given a test of labor to see whether the head will enter the pelvis. If after a reasonable length of time the head fails to enter the pelvis, abdominal delivery is advisable. It is necessary to recognize a disproportion early, else the patient will be permitted to remain in labor a long time, the membranes may rupture, infection may set in and an attempt at forceps delivery be made before the true condition is recognized. It is then too late to deliver a live baby without danger to the mother.

Once the second stage has begun the physician should not leave the patient until delivery has been completed. By the second stage is meant the period which extends from the time of complete dilatation of the cervix to the time the entire fetus is expelled.

When the second stage is reached, the patient and bed should be prepared for delivery and sterile instruments, solutions, cord tie, etc., should be placed near the bed. In multiparous women these preparations should be made before the cervix is fully dilated.

Essentially four main points are to be considered during the second stage, namely, asepsis and antisepsis, anesthesia, protection of the life of the child and the preservation of the perineum.

All are agreed that asepsis and antisepsis are basi principles. In the home they are difficult to carr out; but there is no doubt whatever that they can b practised there effectively. As regards anesthesi there is almost unanimous opinion that women shoul be relieved of the pains of labor as much as possible but various types of anesthesia are employe It is inadvisable to give narcotic drugs such a morphine during the second stage because of th likelihood of harm to the child, even though it slight. Inhalation anesthesia which may be in th form of ether, nitrous oxide and oxygen, ethylene c chloroform may be used. We prefer ether or ethy lene. With the beginning of each uterine contrac tion felt by the hand on the abdomen, a few whif of the anesthetic are given and the moment the hea passes through the vulva, the anesthesia is deepene

It can be said with assurance as regards the pre servation of fetal life, that attention to the child du ing the second stage will save many lives. On should watch carefully for the first signs of asphyxi and this is done by listening to the fetal heart tone every five minutes or oftener when indicated. Fo this purpose we employ the De Lee-Hillis stetho scope (Fig. 1) which rests on the head and can b kept there during spontaneous deliveries and forcep operations. Both hands remain free and sterile a all times even when the fetal heart tones are care fully controlled.

After every spontaneous delivery of a full ter child in a primipara there is some damage to th perineum. The urogenital septum is always rup tured, the connective tissue is torn in many place the layers of fascia are loosened, the levator a muscles are usually lacerated and in general all th tissues are bruised. This condition is usually pre vented by a timely episiotomy which should be performed in most primiparæ with full term babies. If an episiotomy is not done, tears may be minimized by delivering the head slowly and in forced flexion.

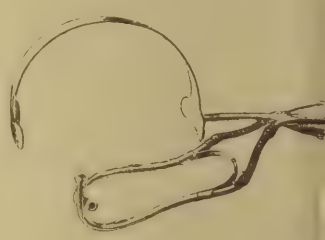

FIG. 2.—Headband of steel.

If there is atony of the uterus and the patient has a pendulous abdomen, a tight binder will help. If there is delay after the head is well down on the perineum, both hands may be spread evenly over the fundus of the uterus and gentle pressure exerted the axis of the outlet; but only during uterin contractions. This method, however, is not witho danger. Episiotomy should not be forgotten a if these measures fail, forceps are indicated. this country, at least seventy-five per cent. of a forceps operations are done for uterine atony.

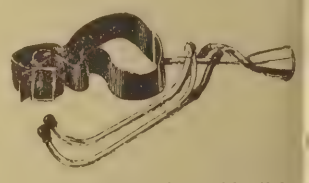

FIG. 3.—Headband of silk, light and transportable.

I have purposely avoided the mention of pituitri

We never use this drug until after the baby is born. The only time pituitrin may be advisable before delivery of the child is for uterine atony in a multipara when the head is on the pelvic floor and the bony outlet is not contracted. Even here we prefer the forceps because we can control the forceps but we cannot always control pituitrin, even with anesthesia. Furthermore, in the cases where the use of pituitrin might come into question, the forceps operations are very easily and quickly performed without injury to mother or child.

In a considerable number of cases, more than is usually recognized, the baby's occiput is posterior. In these cases, labor usually lasts a long time; hence the uterus becomes exhausted and the patient tired out. These patients should be given morphine and scopolamine. Fortunately in most of the cases the occiput rotates anteriorly and delivers spontaneously. Despite this, however, more babies are lost from occiput posterior than from any other one cause (De Lee). This is essentially due to failure in making a correct diagnosis early in labor and yet the diagnosis is relatively easy. Labor pains are usually weak and irregular and early rupture of the membranes is frequent. The head remains high for a long time and dilatation of the cervix is slow because the head does not fit well. Abdominally a distinct hollow may be seen over the symphysis. The heart tones are usually deep in the flank but may be heard on the side opposite the baby's back. The small parts are extremely prominent anteriorly. Internal examination reveals the head high up, partly deflected and the large fontanelle more accessible than usual because it is nearer the centre of the pelvis. The small fontanelle is near the sacrum. If the caput succedaneum is so large that the sutures and fontanelles are hard to identify, locate the ear and feel the tragus. The latter will always indicate the direction of the occiput. If there is no disproportion between the head and the pelvis, the treatment is expectant unless an indication for interference arises.

If in a case of occiput posterior the patient cannot deliver herself spontaneously within a reasonable length of time after the cervix is completely dilated, she should be anesthetized. With the hand, the fetal head should be rotated anteriorly before or after an episiotomy has been performed, then forceps should be applied and the head delivered. When the bag of waters is intact and the head high but there is no disproportion between the head and the pelvis, a podalic version followed by extraction may be performed. If in a case where the head is high and labor has lasted a long time, the cervix is not fully dilated and effaced, especially if the patient is an elderly primipara in good condition, a low or cervical Cæsarean section should be done.

While it is generally advisable to follow a policy of watchful waiting in the second stage just as in the first stage, one should not allow a woman to remain in labor too long. We should not wait to see what a patient can endure but simply what she can accomplish. To wait too long may mean death to both mother and child. On the other hand, because the patient makes a great deal of noise and the family insists that something be done, one should not interfere too soon. If a physician feels he can-

FIG. 4.—The author's anal shield.

not take care of a patient alone he should not hesitate to call for assistance.

The dangers of the second stage to the child are numerous and almost every kind of injury has been caused by the forces of spontaneous labor. In general, four per cent. of all babies die during labor and a fair proportion of these deaths occur in natural unassisted delivery. Neurologists as well as obstetricians have long pointed out the connection between prolonged hard labor and epilepsy, idiocy, cerebral palsy, and other similar conditions. In fact statistics seem to show that proper instrumental delivery is safer than prolonged, hard, unassisted labor; for it seems that the brief and moderate compression of the head in a properly performed forceps operation is less dangerous to the integrity of the fetal brain than the prolonged pounding and congestion it suffers from a hard spontaneous delivery.

Episiotomy likewise saves the child's head from prolonged compression, it shortens the duration of labor, it forestalls asphyxia and it prevents ragged lacerations which are otherwise almost inevitable.

Of the various types of episiotomy we prefer the mediolateral, made at the time the head stretches the levator ani muscles. This is recognized by the opening of the anus and the dislocation of the anus downward and forward. The patient is given a few whiffs of anesthetic as the cut is made and the latter is not repaired until after the expulsion of the placenta. In the home it is better to repair the episiotomy wound with figure of eight silkwormgut sutures which take in all the layers. In the hospital, if the asepsis has been perfect, the structures may be sutured with catgut, layer by layer in anatomicosurgical fashion. Care must be taken to prevent instruments and suture material from coming in contact with the anus. To avoid such contact I devised a small metal anal shield (Fig. 4). By means of a properly performed episiotomy and repair, almost virginal conditions are restored.

When forceps are to be applied, five conditions must be fulfilled: First, there must be no disproportion between the baby's head and the mother's pelvis. Second, the cervix must be completely effaced and dilated. Third, the head must be engaged; that is, the greatest diameter must be below the inlet of the pelvis. When the lowest part of the fetal skull, not the caput, is at the level of the ischial spines, the head is engaged. Fourth, the bag of waters must be ruptured, and fifth, the baby must be living. After the application of the forceps blades and before they are locked, one should listen to the fetal heart tones. If the latter remain regular, the forceps are locked. If the heart tones change, it usually means that a loop of cord is being compressed by the forceps. In this event, the forceps should be removed and reapplied. If the heart tones again change, it is better to deliver the child by version and extraction.

In doing a forceps delivery one should be absolutely certain of the position of the occiput. Palpation of the baby's ears will always verify the diagnosis. The bladder should be catheterized before every forceps delivery. The operator should sit comfortably with his elbows at the side and in making traction he should seldom use more force than is furnished by the biceps muscles. Time should not be considered; but one must listen to the fetal heart tones after every traction or two. Traction should be intermittent and not accompanied by pendulous or twisting motions. In primiparæ an episiotomy should be performed, preferably after the application of the forceps to avoid an unnecessary loss of blood.

In breech cases a policy of expectancy should be followed unless an indication for quick delivery arises. In multiparæ little trouble will be encountered usually, but in primiparæ there is a large fetal mortality and morbidity and a high maternal morbidity. One should not interfere until the baby's buttocks have been delivered over the perineum, unless a definite indication arises. In all primiparæ if the baby is large, a deep episiotomy should be performed. Great haste is not essential and care should be taken to avoid fractures. Pulling on the child's neck is bad practice as it may result in Erb's paralysis, fracture of the cervical vertebræ and other injuries. Pressure on the child's head from above is the essential thing in the delivery of the after coming head; but the pressure should not be exerted blindly. The head must be in the proper attitude before aid is given from above and much force should never be used. If the head is in the pelvic cavity and difficulty is encountered, one should not use force but forceps should be applied to the after coming head. Hence, before doing a breech extraction (or a version and extraction) a pair of forceps should be sterilized with the other instruments.

Face presentations are usually delivered spontaneously with the chin anterior. Delivery of a full-term child with the chin posterior, either spontaneously or instrumentally, is almost out of the question. If forceps are to be applied, the chin must be rotated anteriorly or at least to the transverse diameter. One may convert a face presentation into an occiput presentation or do a version and extraction. In all cases where the face is delivered first, a deep episiotomy should be performed.

Immediately after a baby is born, regardless of the type of delivery, it is a good plan to give the mother an ampoule of pituitrin. This hastens separation of the placenta and saves blood.

The management of the third stage of labor is more important than most physicians realize, for more women die from accidents occurring in the third stage than during the other two combined. One should treat the third stage as follows: After the child is born, place the hand on the uterus but do not massage. Wait until signs of placental separation have occurred. These are, advance of the cord from the vulva, rising of the uterus in the abdominal cavity, change in shape of the uterus from a globular one to one with a sharp ridge at the fundus and diminution in size and hardening of the uterus. When these signs are noted, gentle pressure on the contracted uterus will readily expel the placenta. If after one hour the placenta does not separate, the Credé method may be used, first making sure the bladder is empty and the uterus well contracted and in the midline. After delivery of the placenta and membranes, they should be examined for missing pieces. In the home it is best not to invade the uterus for missing pieces of membrane unless there is hemorrhage; but pieces of placenta had better be removed without delay. Never pull on a cord to deliver the placenta. If a placenta is adherent and manual removal must be done, the strictest aseptic precautions should be taken. The gloves should be changed before invading the uterus and it is a good plan to give the patient ergot during the first few days of the puerperium. We give nearly all patients ergot immediately after the placenta has been delivered.

If hemorrhage results after expulsion of the placenta and membranes and the latter are complete, the bleeding is due to lacerations or to atony of the uterus. If due to lacerations, immediate repair should be done. If due to atony, indicated by flabbiness of the uterus, and if pituitrin and ergot given hypodermically do not suffice, also if pituitrin given into the uterine muscle through the abdominal wall does not help, the uterine cavity should be packed tightly with gauze. Asepsis should not be sacrificed for speed in an effort to save blood.

When the third stage is over, the perineum should be carefully inspected for lacerations and if any are found they should be repaired immediately. Episiotomies should be repaired at this time also.

If a child is born asphyxiated, it is not necessary to use forcible means to resuscitate it. First of all, warmth is essential; hence a towel, preferably a warm one, is wrapped around the baby. The respiratory passages must be clear and if it is necessary to clear them artifically the best means is a tracheal catheter. If respirations do not begin after this, air should be blown into the child's lungs through the tracheal catheter but with extreme gentleness. These measures will resuscitate practically every baby which can be reanimated.

Before leaving a patient's home or hospital, the physician should assure himself that the mother and child are in good condition. The uterus should be firm, there should be no hemorrhage, the placenta and membranes intact, and the mother's temperature and pulse recorded. The child should be examined to see if it is breathing properly, if its color is good, its cord properly tied, and whether fractures are present. The instillation of silver nitrate should not be forgotten.

During the puerperium, the patient should be carefully watched. The diet should be looked after and also the bladder and bowels. The uterus should be palpated and the lochia observed. The breast and nipples should be given consideration and the temperature and pulse properly recorded.

After discharging a patient, it is advisable to tell her to return for an examination at the end of six or eight weeks. At that time, a pelvic examination will reveal whether involution has taken place, whether the uterus is retroverted and the result of the perineal repair if any had been done.

In closing, I should like to emphasize the present unnecessarily high maternal and fetal mortality and morbidity. Physicians can reduce this considerably by careful observation of their patients during pregnancy, by the proper management of labor and above all, by the education of their patients.

The Clinical Aspects of Abortions*

PHILIP F. WILLIAMS, M.D.
Philadelphia

When the advocates of birth control can offer an absolutely efficient contraceptive, when the moral attitude and economic situation of the public renders the criminal abortionist an unnecessary element in our midst, and when the practice of obstetrics has reached the perfection of carrying every pregnant woman through to a normal postpartum condition, then, and then only, may we expect a reduction in the present number of abortions. Such a Utopian state of affairs is so far away in the dim future that the problem of interrupted pregnancy in many of its aspects is still a fruitful source of medical and, at times, legal discussion.

The clinical picture presented by a large group of aborting women has seemed of sufficient interest to warrant my presenting it. I am indebted to Dr. J. H. Girvin, chief of the Gynecological Service at the Presbyterian Hospital, for the privilege of reviewing the histories of one hundred cases of abortion occurring in his service. These histories form the basis of my study.

The ages of these women when arranged graphically show two peaks; one high sharp point at the age of twenty-three, and a second sharp incline to an apex of thirty years of age with a broad drop through the next two years. A survey of the histories of the women in these peaks reveals definitely that the first contains a large number of primiparæ in whom the abortion had been induced, either by themselves or others, and that the second includes mostly multiparæ, who presented varying degrees of pelvic pathology, uterine displacements or residual low grade inflammations of the pelvic organs.

We found that in the abortions studied it was the first pregnancy in twenty-one women, all under twenty-five years of age, and in nine of these the abortions were admittedly criminal. In the seventy-nine multiparæ it was the second pregnancy in twelve, the third in fifteen; and the relation of the number of abortions past and present to the births at term agrees with the generally accepted ratio of one abortion to four births at term. In other words about twenty per cent. of all pregnancies are interrupted. A survey of the social status shows but two single women, and both presented febrile criminal abortions.

Duration of Pregnancy

The duration of the pregnancies indicated that the majority, eighty per cent., aborted during the second and third months, only one carried as far as the fifth month. The presence of the fetus was noted twenty times, either expelled after admission or removed in a few cases of inevitable abortion at operation. In eleven instances it was noted that the fetus had been passed before admission. This interesting fact, that the fetus is seen in but one third of the cases, supports the observation of Meyer, who studied the material at the Carnegie Institute of Embryology, and concluded that the death of the fetus preceded the clinical manifestations of a spontaneous abortion by an average of six weeks. The fetus, macerated or disintegrated by such a long period of autolysis, might easily escape notice in many cases.

The previous medical history of the cases where induction might reasonably be excluded was inquired into. In a period of five years before conception in the primiparæ, or since the last pregnancy in the

*From the Gynecological Service of the Presbyterian Hospital, Philadelphia. Read before The John Morgan Medical Society, December, 1924.

multiparæ influenza had occurred in nine, pneumonia in four, tuberculosis in three, heart disease in two, and tonsillitis and lues in one each. It is difficult to ascribe the effect of any of these diseases as an etiological factor, except in the one case where pneumonia complicated a five months' pregnancy. Syphilis seems to be a negligible factor in the production of abortion. In but one case was the history of specific infection elicited; here the Wassermann reaction was positive. In seventy-four other cases the Wassermann reaction was negative.

PREVIOUS SURGICAL OPERATIONS

Surgical procedures had been previously performed in twenty-six of these women. Six can be immediately eliminated, as criminal induction was admitted. In nine cases where plastic operations on the perineum or cervix, with or without suspension of the uterus or appendectomy, no cause could be assigned for the abortion, except in one case where the woman had fallen down a flight of stairs. Five women had been previously curetted, with or without accompanying suspension of the uterus, salpingectomy or appendectomy; in none could a cause for the abortion be given. In the remainder, six in number, abdominal operations, not for pelvic disease, had been performed, and in them no cause could be assigned for the abortion. In most of these cases pelvic examination under anesthesia disclosed little pathology; in two cases definite evidence of gross pelvic pathology, not associated with the previous operation, was present. Presumably in some others the indefinite residuum of previous pelvic or uterine disease had been sufficient to prevent a long continuance of the pregnancy. As an evidence of old endocervicitis and presumably some degree of endometritis it may be added that in over half of the cases in the series the patients complained of a marked degree of leucorrhea.

CAUSES

When the possible cause was questioned for, or when this was stated, it was found that criminal induction had been performed in thirty-four cases, no cause could be assigned in fifty-two, heavy labor or trauma of various sorts in eight, while fibroid tumor, pneumonia, pernicious vomiting, cervical implantation, missed abortion and fright completed the list. In the cases where no cause could be given by the patient retroflexion of the uterus was present in ten, laceration of the cervix and endocervicitis in four, prolapse of the uterus in one and traces of old pelvic peritonitis or cellulitis, as evidenced by fixation, scars or tenderness in three cases.

In many of these cases the patients showed an anemia. Seven had below forty per cent. hemoglobin, nine below fifty per cent., and seventeen below sixty per cent. A total of sixty-one patients showed a hemoglobin of seventy per cent. or less. In three of these cases transfusion was performed, in most of the others iron and arsenic was exhibited by hypodermic during their stay in the hospital and various hematinics while they remained under observation.

An abortion was considered as febrile if a temperature of 100.4° or higher, sustained for twenty-four hours, was recorded. There have been twenty-eight such cases in the series, in fourteen of them the abortion had been induced. Blood cultures were taken thirty-seven times in these febrile cases. In two the cultures showed hemolytic streptococci, both patients recovered with the administration of antistreptococcus serum, in addition to other measures. In practically the whole series a culture was made from the interior of the uterus at the time of operation, or from the cervix if not operated upon. Fifteen positive results were reported by the laboratory in eight the abortion had been induced, in six the abortion was febrile. The Staphylococcus aureus was found nine times, the Bacillus coli five times, and the Streptococcus hemolyticus and nonhemolyticus once each. No positive blood cultures were found in these cases of positive uterine cultures. The findings here are of apparently negative value but may at times explain the origin of a blood stream infection.

SURGICAL TREATMENT

Eighty-eight patients were operated upon. This operation consisted of the early digital and instrumental evacuation of the uterus, with a blunt placental forceps; in a few cases a dull curette was used. Operation was delayed a short time in a few febrile, apparently septic, cases for the purpose of observation. The twelve cases in which the patients were not operated on include nine apparently complete abortions, one inevitable abortion, complete after packing for hemorrhage, and two threatened abortions, in both of which there was a history of attempted criminal induction.

The effect of early operation in twenty-five febrile cases has been a rapid lowering of the temperature to normal, within forty-eight hours in sixteen cases. In two cases of criminal abortion the temperature remained elevated for fourteen and twenty-one days, the uterine cultures showed Staphylococcus aureus and Stereptococcus hemolyticus in one, and Bacillus coli in the second, in which there was an associated pelvic cellulitis. In no instance has the removal of the uterine content in a febrile case given rise to a blood stream infection. In one case in which the patient was afebrile on admission and at time of operation, a postoperative fever three days later was due to a blood stream infection with the Streptococcus hemolyticus. This cleared up under serum treatment.

In the second case, in which also the patient was afebrile on admission and at operation, a marked temperature rise for three days with sterile blood cultures was observed. The careful emptying of the uterus in spite of a mild fever rids the woman of a focus of infection, for the most part of low grade virulence, favors involution of the uterus, and quickens convalescence, with a shorter stay in the hospital. The duration of the hospitalization ranged from five to fifty-two days, the latter in a case of pneumonia, with an average of twelve days for all cases.

Histological examination of the specimens removed at operation disclosed nothing noteworthy. Spirochetes were not found in any of the fetuses or other tissues when searched for. Fibrosis of the chorionic villi, infection and various stages of degeneration of the decidua have been noted.

Eye Changes in Pregnancy

JOHN M. WHEELER, M.D.
New York

CONTRACTION OF THE VISUAL FIELDS FROM ENLARGEMENT OF THE HYPOPHYSIS

That pregnancy is responsible for enlargement of the pituitary body has been demonstrated satisfactorily. In 1922 Finley of Havana reported "that during pregnancy there often occurs, as a result of the normal hypertrophy of the pituitary gland in connection with this state, a compression of the chiasm which manifests itself by changes in the visual fields in the nature of a bitemporal contraction, which varies in degree according to the amount of compression suffered, this depending on the corresponding amount of hypertrophy and on the anatomical peculiarities of the case which may favor or hinder this compression."

There is no impairment of the central vision due to the hypophyseal enlargement and the fields are not contracted enough to interfere with the patient's getting about safely. The phenomenon manifests itself during the last few weeks of pregnancy, and disappears after parturition. It occurs in primiparæ and multiparæ. While this condition is interesting, it probably is not of great importance in its immediate manifestations, and it is believed that there are no unfortunate late results.

ATROPHY OF THE OPTIC NERVE

Rarely optic nerve atrophy unassociated with retinitis develops late in pregnancy. This is thought to be the result of retrobulbar neuritis caused by the toxemia of pregnancy. It may result in partial or complete pallor of the nerve heads with partial or complete blindness. With the knowledge that the hypophysis is enlarged late in pregnancy it may be well for us to have in mind the possibility that in rare cases the enlargement might be great enough to cause pressure atrophy of the chiasm and optic nerves.

CHOROIDITIS

Although not generally recognized as a manifestation of toxemia of pregnancy, I think that choroiditis should be given a place among the important eye conditions caused by the gravid state. I have seen several cases of well developed exudative inflammation of the choroid in pregnant women who were sound except for their pregnant condition. The choroid is a highly vascular structure, and pathological response to pregnancy toxemia should not be considered a strange thing. In choroiditis the prognosis as to vision depends upon the location of the lesion. The portion of the retina which corresponds to the choroidal lesion is robbed of its function. If the lesion is in the macula, which provides central vision, serious permanent impairment of sight will result; but if the choroidal inflammation is away from the macula, the resulting blind area will not be important. Fortunately, the choroiditis most often affects only one eye, so there is small chance of serious impairment of sight in both eyes. In cases of development of choroiditis in both eyes or in a patient's only good eye, induction of labor might be wise.

SPASM OF ACCOMMODATION

Rarely the pregnant woman may be alarmed by impairment of her distant vision due to overaction of the ciliary muscle, resulting in the equivalent of myopia. She sees well (perhaps better than normal) for reading, but at a distance her sight is blurred, and it may be necessary for her to wear concave lenses in order to have good distance sight. Presumably toxic substances stimulate the muscles of accommodation to a condition of mild spasm. The condition may continue for a few weeks after delivery, but relaxation gradually returns without serious consequences.

HEMORRHAGIC RETINITIS

This is the best known eye complication of pregnancy, and the most important. Its presence may carry heavy weight with the obstetrician in his decision to induce labor, both because of its danger to the patient's sight and because of its significance in regard to the general condition of the patient. Without going into technical detail, it may be said that there are two types of retinitis in pregnancy, one associated with acute toxemia and the other with chronic cardiorenal disease. The retinitis appears during the latter part of pregnancy, and may occur in either primiparas or multiparas.

Each case of pregnancy with hemorrhagic retinitis should be judged by itself, but it can be said that the development of retinitis is always of serious import, and usually indicates prompt termination of labor. It is not necessary for me to say here that the lives of both mother and baby are at stake. As to the mother's eyes it may be said that some danger always results from retinitis. Blindness either complete or partial in both eyes is the usual outcome if the condition is allowed to remain long. In some cases, however, the optic nerve and retina are not badly injured and useful vision may result. Fortunately, the development of retinitis in one pregnancy does not mean that it will appear in succeeding pregnancies.

UREMIC AMAUROSIS

While all obstetricians are familiar with hemorrhagic retinitis of pregnancy many do not know of the rarer condition of uremic amaurosis, quite a different sort of a process. In this condition the patient loses the sight in both eyes, but ophthalmoscopic examination reveals nothing abnormal. The blindness is due to the toxic effect of uremia on the brain cells and not to involvement of the optic nerves or eye structures. Inasmuch as the process is supranuclear the pupils react to light, both directly and consensually, although the patient is blind. If the patient recovers from her uremia the sight is surely restored, and in this regard the prognosis is quite different from that in albuminuric retinitis.

30 West Fifty-ninth Street.

Gonorrhea in Women*

BERNARD MANN, M.D.
Philadelphia

Considering its prevalence and its farreaching influence on the health and bodily resistance of the subject, gonorrhea in women must be regarded as one of the most important gynecological diseases. Because of the greater complexity of the female genital tract, this disease is far more varied and dangerous in women, both to life and health, than in men.

Neisser states that with the exception of measles, gonorrhea is the most widespread of all diseases. "It is the most potent factor in the production of involuntary race suicide, and by sterilization and abortion does more to depopulate the country than does any other cause (Norris). There is probably no other disease that has caused as much suffering and sorrow throughout the world as has gonorrhea.

Nöggerath said that in New York city eight hundred out of one thousand married men have gonorrhea; that ninety per cent. of all these have not been cured and can infect their wives; that in New York eighty per cent. of married women, at least, have gonorrhea, or the results of it. While, at first glance, this seems an extravagant statement, our own observations tally with Nöggerath's conclusion (Polak).

In France, where statistics have been accurately compiled, it has been found that of ten million families, two millions are without issue; these results, according to Neisser, would tend to show that gonorrhea is the etiological factor in nearly one million sterile marriages, and this does not include the vast number of "one child sterilities" due to this cause.

The period of inoculation with gonorrhea varies from twelve hours to a week. The part most likely to be infected depends largely on the point of contact. If the introitus is small, the urethra and Bartholin ducts are most liable to be the seat of the initial lesion; while in the parous woman the cervix is most often the seat of the primary infection. The infection almost invariably begins as a surface inflammation, and spreads more or less deeply into the underlying structures. The gonococcus may lie dormant in the cervical glands for a prolonged period and spring into activity under proper stimulus. On the other hand protracted encapsulation, such as often occurs in the adnexa, tends to destroy the organism.

Gonorrhea may exist in the genital tract during the period of pregnancy without clinical manifestations and become active during the puerperium; this explains some of the late postpartum infections. It has been proved that by passing gonococci through a second subject they may acquire added virulence; this explains how an apparently cured subject of chronic or latent gonorrhea may infect his wife, and in turn be reinfected by her. The virulence of the gonococcus is increased by menstruation and during pregnancy, fortunately the dried gonorrheal secretion is innocuous. Married persons infected with the gonococcus may become more or less immune to their own particular organism, so that the symptoms and signs of the disease may subside completely. If these persons live apart from each other for a considerable period of time, upon resuming sexual intercourse a violent gonorrhea may be set up in either one, although both have been virtuous during separation. Or if the infection is transferred from a married couple to a third person and then again to one of the original incumbents, the gonococcus will have become more virulent and is capable of producing a violent fresh infection in the recipients. There exists to the gonococcus no immunity such as belongs to most other microbic organisms.

Under ordinary conditions the gonococcus rarely produces serious lesions in localities invested by adult squamous epithelium such as the vagina, the inflammatory reaction being due to the toxin laden discharge from the lesion higher up. In the cervical and corporeal mucosa, however, a different condition exists; the surface epithelium becomes swollen and the cells become separated from one another by the inflammatory exudate, desquamation takes place, and many of the cells are replaced by a modified epithelium, or cicatricial tissue may result. The gonococci quickly gains access to the glands and similar changes occur in the investing cells; and the exudate is poured out into the periglandular tissues, so that the gland openings become occluded and filled with inflammatory exudate, with the formation of pseudoabscesses. As the process advances, the epithelium and its basement membrane may be entirely destroyed, and a true abscess surrounded by a pyogenic membrane may form. Such is the pathology of an abscess of Bartholin's glands or of occlusion cysts in the cervix. Gonococci in the glands may persist long after a surface cure has been effected; and from this location reinfection frequently occurs. This tendency to glandular penetration, which is possessed by the gonococcus, accounts for the resistance of the coccus to gonococcides applied to mucous surfaces. From the surface and gland crypts the gonococcus escapes into the stroma and underlying muscular layer, and in severe tubal infections even unto the serosa and adjacent structures. This migration excites a local tissue reaction, so that the submucous structures become swollen and infiltrated with inflammatory products and the contiguous bloodvessels become intensely congested. These reactionary changes vary with the severity of the infection, the stage of the disease and the anatomical character of the tissue involved. The underlying swelling and edema are accountable for a desquamation of the surface epithelium and distortion of the parts by the long continued inflammation in the depths of the mucosa with the formation of cicatrices, which interfere with the lymphatic drainage and consequently allow a continuance of the symptoms after all signs of active inflammation have subsided.

This is particularly evident in intraperitoneal pelvic lesions where adhesions and contractions so distort the pelvic anatomy that operative measures for relief must be instituted for the patient's comfort and health, rather than for the cure of the infection.

*Read before the Medical League, Philadelphia, November 24, 1924.

The most marked pathological changes are usually found near the surface, as the tissue in this locality seldom undergoes complete resolution. The chief characteristic of gonorrheal inflammation is its chronicity.

The foregoing will suffice as an introduction to the presentation of the symptoms and treatment of the various organs involved.

INFECTIONS OF SKENE'S GLANDS

Skene's glands, or the paraurethral ducts, are two small tubules which lie on each side near the floor of the female urethra and extend up from the meatus urinarius for about three fourths of an inch; these ducts open just anterior to the centre of the urethral lips. Their chief interest lies in the fact that gonorrheal invasion of these ducts is the most persistent lesion with which the gynecologist has to deal, for the gonococcus may remain indefinitely buried beneath the lining cells of the tubule and may cause a chain of symptoms referable to the urinary tract, as chronic urethritis, with its frequent and burning urination, or a persistant infective discharge, which in turn carries the infection higher up to the cervix. The diagnosis is made by exposing the mouth of the tubules, a finger in the vagina making pressure against the urethra from within outward along its course. A drop of pus may be expressed from the mouth of each tubule. The presence or absence of the gonococcus should always be demonstrated in the pus by the microscope.

Treatment.—After cocainizing the meatus and the urethra by inserting into the urethra a pledget of cotton wet with a ten per cent. cocaine solution, which is left in place for about ten minutes, a probe pointed hypodermic needle is inserted into the duct, and a drop of carbolic acid, or twenty-five per cent. silver nitrate solution, is injected into the tubule. This treatment may have to be repeated several times at intervals of a week. A more satisfactory method is splitting open the ducts with the electric cautery.

INFLAMMATION OF BARTHOLIN'S GLANDS

Bartholin's glands are two compound tubular glands situated one on each side of the posterior commissure of the vaginal orifice, their physiological function being that of lubrication. The infection is usually secondary to an infection elsewhere, especially in the urethra. They are rarely infected by any other organism than the gonococcus, so that an inflammation of them constitutes an almost unmistakable stigma of gonorrhea. The initial infection takes place in the short duct of the glands. The infection then extends to the main part of the glands, and an abscess is established which may become acute at once or lie dormant to light up at some later period. As a rule only one gland is affected, but both glands may become inflamed.

The clinical picture of an abscess of Bartholin's glands is characteristic. The patient complains of a vulvar swelling on one or both sides of the labia minora. There is exquisite pain and tenderness, which are rendered worse by friction or walking and are partially relieved by rest and with the thighs separated. On inspection, the usual evidences of inflammation, such as redness and swelling, are to be seen. The orifices of the duct or ducts are red and swollen, and there is an ovoid tumor in one or both labia, more or less occluding the orifice of the vagina. The overlying tissues of the labia are red, hot and painful, and the tumor rapidly enlarges, the enlargement extends backward toward the commissure and upward into the submucous tissues of the vagina. There is usually a slight elevation of the temperature.

Treatment.—This consists of complete excision of the gland. Simple incision, cauterization, and drainage rarely effect a permanent cure. At the present time I have a patient who refused excision of the gland, but was compelled to have an abscess incised three times, at six and eleven month intervals.

GONORRHEAL URETHRITIS

The picture of a well-defined gonorrheal urethritis is characteristic and almost pathognomonic. The vestibule is reddened and tender and bathed in pus. The meatus is pouting and swollen, while from the urethra can be expressed a thick creamy pus, a smear of which shows the gonococci.

The symptoms produced in a typical case in the female is quite similar in its initial symptoms to that in the male. There is first a sense of discomfort and then a burning from urination, followed by a purulent discharge. This pain on urination is sometimes extremely severe, and may be accompanied by ulceration and bleeding from the urethral mucous membrane. The duration of the average case is from three to six weeks, but the acute symptoms usually last only a few days. The disease has little tendency to ascend in the urinary tract unless carried by improper local treatment. Occasionally gonorrheal urethritis becomes chronic but when this happens there is usually an associated inflammation of Skene's glands, which has an influence in maintaining the persistence of the urethritis.

Treatment.—The local treatment is best carried out by injecting silvol five to ten per cent. into the urethra, care being taken not to force the solution into the bladder. The patient should urinate just before the injection and should abstain from urinating for at least an hour afterward. The solution used should be of such strength as the patient can tolerate without pain. Alcohol must be avoided. An abundance of water should be drunk. To guard against cystitis, five grains of hexamethylenamine or ten grains of helmitol may be given. No douching should be employed. The vulva should be cleansed every three hours with warm boric acid solution.

VULVOVAGINITIS IN CHILDREN

Primary gonorrheal infection of the vulva and vagina is a disease which affects children or young girls almost exclusively. This is due to the fact that the modified squamous epithelium of the vulva and vagina in children and early youth is soft and delicate. It is extraordinarily susceptible to gonorrheal infection. As the child develops into adult life the surface epithelium of the vulva and vagina becomes somewhat cornified and more resistant, so that in adult life a primary infection of the vulva or vagina is rare.

The mode of infection of vulvovaginitis in children is often difficult to determine. A few cases can be traced to depraved sexual practices. The children of gonorrheal parents are exposed to infection by contaminated towels, sponges and bed linen. The lochial discharge of a puerperal woman in whom childbirth

has lighted up a latent gonorrhea is a frequent means of infecting the child. Such sources of infection as these just enumerated are sufficiently obvious, but when gonorrhea makes its appearance and extends from child to child in carefully regulated institutions, such as hospitals and schools, the mode of infection is often puzzling and difficult to trace.

The clinical picture of a child with gonorrheal vulvovaginitis shows much swelling and redness of the external genitals, associated with pains and extreme tenderness. The parts are continually bathed with a profuse discharge of pus. The disease, like all forms of gonorrhea, is apt to last for weeks and months, if not promptly treated at its onset. The disease has little tendency to ascend above the vagina into the uterus and tubes, but much damage may be done in the vagina as a result of the tendency to ulceration of the vaginal membrane with consequent plastic adhesions between opposing surfaces. Various complications may arise. The urethra is infected, the cervix may become involved, less frequently cystitis, inguinal adenitis, bartholinitis, condylomata acuminata, arthritis, ophthalmia, and proctitis. General peritonitis is occasionally seen, rarely the result of upward extension through the uterus and tubes, more commonly the outcome of a gonorrheal septicemia (Norris).

Gonorrheal peritonitis is peculiarly favorable in its prognosis, and if a diagnosis can be made, should be treated conservatively.

Treatment.—The treatment of gonorrheal vulvovaginitis in children is difficult and requires great care and patience. During the acute stage there is often so much pain and tenderness that it is impossible to do more than keep the external genitals clean. When the more acute pain has subsided somewhat, a five to ten per cent. solution of silvol may be injected into the vagina and cleansing douches be given. A one per cent. mercurochrome ointment has given good results. If this can be done in conjunction with rest and strict cleanliness the disease can usually be quickly controlled, though it may be long before it is completely cured. It is needless to say that most of these cases are badly neglected if they do not receive hospital treatment.

VULVOVAGINITIS IN ADULTS

In the adult gonorrhea of the vagina is usually secondary to an infection beginning elsewhere. In the acute gonorrheal form a history of a suspicious intercourse is always suggestive; the discharge is profuse and of purulent character, yellowish or greenish in appearance. The urethra and the urethral glands are usually involved, so that frequent and burning urination is the rule. Fresh pus may be expressed from the ducts of Skene's and Bartholin's glands. The vaginal mucosal membrane is dark red or bluish in color, is more or less thickened and studded with patches of erosion which bleed easily.

The patient will complain of a throbbing sensation in the perineum, backache, and a feeling of heat and pain in the vagina. No positive diagnosis should be made unless the gonococcus can be demonstrated microscopically.

Treatment.—Rest in bed and a posture (Fowler position) that is comfortable to the patient and insures free vaginal drainage; no douches or irrigation should be given in the early stages. A twenty-five per cent. solution of silvol may be poured into the vagina. When the acute stage has been passed, douches may be given, and topical applications of silvol and similar remedies. Dibromin one to ten thousand as a douche has given good results.

GONORRHEAL ENDOCERVICITIS

The vaginal portion of the cervix at the external os is a common seat of gonorrheal infection in married women, for if the introitus is relaxed, the cervix becomes the first point of contact and is frequently directly infected at coitus. According to Menge, cervix infection is found in about eighty per cent. of all acute cases, and in ninety-five per cent. of chronic cases.

When the cervix is infected in the acute stage, there is a profuse mucopurulent discharge which fills the upper part of the vagina, the cervix is swollen and tender to the touch, and as a result of the hyperemia and swelling of the mucosa of the canal, the mucosa tends to evert and project itself beyond the external os. Menstruation may be irregular, painful and profuse.

Treatment.—In the acute stage the treatment is the same as in acute vaginitis. Later after the acute symptoms have subsided a twenty-five per cent. silvol solution is useful, and vaginal irrigations of bland antiseptic solutions may be used.

CHRONIC ENDOCERVICITIS

Chronic endocervicitis is the most prevalent of all gynecological disorders. There is a persistent irritating leucorrheal discharge which the patient has difficulty in controlling, even with numerous douches. Douches have no curative effect on the disease, as they do not reach the seat of infection, they merely cleanse the vagina. The influence of this constant leucorrheal discharge often has a disastrous effect on the nervous system of the patient, especially if she is aware of the original cause of her trouble.

In some of the glands the inflammatory process may cause a closure of the duct. The gland continuing to secrete without an outlet becomes a retention cyst. The endocervix is a favorite and treacherous place for the latent gonococcus to lurk, either in the folds of the lining membrane or in the ducts of the glands, ready to light up into later infectious activity under the hyperemic influence of coitus, menstruation or childbirth.

Treatment.—As mentioned before, douches serve only to keep the vagina clean. The treatment must be applied directly to the cervical canal. Whatever form of local treatment is instituted during the chronic stage, it is of the utmost importance, as a preliminary step, that the thick cervical mucus be removed. Its presence acts as a protective medium for the gonococcus, and prevents the application from reaching the diseased areas.

Tincture of iodine or ten per cent. silver nitrate solution applied to the diseased area and to the canal will at times effect a cure after repeated applications. Very good results are obtained from the linear cauterization, but this treatment may cause scars and interfere in future childbirth. In a few cases I have used radium with good results.

Corbus and O'Conor report very good results in the treatment of cervical gonorrhea by diathermy. B. C. Hirst, who has used this method of treatment,

is well pleased with the results thus far obtained. Before the heat is applied the endocervix should be thoroughly dried, and tincture of iodine or ten per cent. silver nitrate applied to the canal.

ACUTE GONORRHEAL ENDOMETRITIS

Involvement of the corporeal endometrium is invariably an extension upward of the cervical infection. The infection usually manifests itself shortly after a labor, an abortion, or just after a menstrual period, or the infection of the endometrium may occur during menstruation, for at these periods the open cervical canal favors the extension of the infection from below. There may be chills and fever, nausea and vomiting. The woman usually complains of pain over the lower abdomen, most marked over the region of the uterus, and some menstrual irregularity is frequently observed. The discharge is copious and thin but when it becomes mixed with the cervical discharge it becomes mucopurulent. The uterus is slightly enlarged, softened and tender, while the cervix which invariably participates when the body is infected, is hypertrophied and tender, and the cervical canal is more patulous than normal.

Treatment.—This is mainly expectant. The Fowler position will aid drainage, ice bags may be applied to the lower abdomen, and cleansing vaginal irrigation once or twice a day. The acute symptoms usually subside in about a week.

CHRONIC GONORRHEAL ENDOMETRITIS

This may occur as a sequel to an acute infection, or originate as a subacute process. When it does occur it is always associated with gonorrhea of the cervix, acute exacerbations frequently follow intrauterine applications or instrumentation, particularly when these manipulations occur near a menstrual period or after a miscarriage. The most constant symptom is leucorrhea, which is whitish or yellowish in color and thinner than that originating in the cervix. Menstrual disturbances are frequent.

Treatment.—The disease for the most part is treated in connection with chronic adnexal disease, with which it is usually associated. Curettage may be done with applications of tincture of iodine. The danger of lighting up the latent infection should be kept in mind.

GONORRHEA OF THE FALLOPIAN TUBES

Tubal gonorrhea is usually an extension of the infection from the uterine endometrium. The disease is usually bilateral, a different degree of pathology may exist in each tube; as, for example, one tube may be the seat of a suppurative salpingitis, while in the other the infection may have terminated in a pyosalpinx.

ACUTE GONORRHEAL SALPINGITIS

All cases of gonorrheal salpingitis are accompanied by a greater or less degree of pelvic peritonitis. The subjective symptoms are fever, pelvic pain, leucorrhea, and a bloody vaginal discharge. The pain and tenderness are diffused over the lower abdomen and are often severe. The pain is increased by muscular exertion, coughing or a jar. There is leucocytosis.

Bimanual examination shows a fixed uterus, excessive pain on touching either vaginal vault, early in the attack a mass is rarely palpable. The abdominal end of the tube is still open and the tube is moderate in size, and the excessive tenderness prevents any deep examination. Owing to the tendency of the inflamed tube to fall into Douglas's pouch, rectal tenesmus is frequently complained of. As the severity of the acute symptoms subside, it may be possible to recognize on bimanual palpation an inflammatory mass in the region of the appendages.

Treatment.—Acute gonorrheal salpingitis is rarely fatal, the disease usually subsides in one or two weeks. The treatment, therefore, is expectant. Rest in bed, liquid diet, hot vaginal douches two or three times daily, ice bag to lower abdomen and the bowels kept open. Operation should not be performed until the temperature has been normal for at least one week. If there is a bulging mass in Douglas's pouch vaginal puncture is the proper procedure, otherwise abdominal section is necessary. Surgery is indicated when a tubal mass is palpable or when palliative treatment has failed to give relief.

CHRONIC PELVIC INFLAMMATION

There is a history of leucorrheal discharge, usually of long standing; repeated attacks of sharp pain, recurring at intervals; there is a constant dragging pain in the lower abdomen, which is increased by the premenstrual congestion, and is relieved by the flow, and returning when the flow ceases. Disturbances of menstruation are common. Pain is increased by any muscular exertion, coitus or defecation. Pain is often referred to distant regions, as headache, backache, etc. These patients are usually neurotic, have digestive disturbances and chronic constipation. Most women with this disease are sterile.

Abdominal palpation shows marked tenderness on deep pressure over the lower abdomen, on bimanual examination the uterus will be found fixed and immovable; there is a hard, irregular, sensitive mass behind the uterus, or to either side of it. Pressure on the tubes always causes severe pain. The cervix is usually eroded and there is profuse leucorrhea.

Treatment.—Where a large tubal mass is palpable and in cases with great pain unrelieved by treatment, operative treatment is indicated. It is impossible, before operation, to judge how much must be removed. I have often been confronted with the problem, especially in young women, as to the advisability of removing both tubes. It has been my experience, that when at the request of the patient, who desires children, and was satisfied to take the risk of a second operation and the tube was the seat of even a slight gonorrheal infection, if such a tube is not removed it will usually cause trouble. The probability of pregnancy is remote, and if it does take place it may be an extrauterine pregnancy. As a rule both tubes are hopelessly involved, and frequently a tuboovarian abscess is formed, and the resulting adhesions require a radical operation.

OPHTHALMIA NEONATORUM

Through education of the physician and the people in general, ophthalmia neonatorum has been greatly reduced. Patients frequently request that the babies' eyes should be given prophylactic treatment. I believe that with continued effort on our part, and persistent demands that both the man and woman be thoroughly examined before marriage and that boys and girls be taught the grave danger of this plague, gonorrhea may be retarded in its ravages.

1619 Spruce Street.

Inflammatory Disease of the Cervix Uteri

JOHN F. McGRATH, M.D., F.A.C.S.
New York

Admittedly it is extremely difficult or almost impossible to bring to light a new truth in the pathology, diagnosis and treatment of such an old, long recognized entity as inflammatory disease of the uterine cervix. But the progress of preventive medicine has made necessary the frequent résumé of accepted opinions and the restatement of proved conceptions concerning a disease which is perhaps the most common of all to which the female sex is exposed.

A study of more than three thousand consecutive cases examined in the Gynecological Department of the Cornell University Medical College Clinic showed the incidence of cervical disease, either as an entity or as associated pathological condition, to be more than sixty-four per cent.

In infancy and childhood it may be associated with the common vaginitis concerning the pathology and sequelæ of which we know so little. It is so prevalent during puberty that a moderate amount of leucorrheal discharge is looked upon by many as a normal prerequisite to proper sexual development. Married women during childbearing life, because of trauma, infection and other reasons incidental to pregnancy and its possibilities, show the highest frequency. But virtuous spinsters are not exempt and present types of the disease that are often most difficult to cure. And again in old age, atrophic cervicitis is not an uncommon nor an unimportant condition.

The etiology of cervical disease is most commonly bacterial invasion of its cellular structure, from a point lower in the genital tract. Except in the case of specific inflammation, however, there are predisposing factors which play important rôles in the incidence of the disease. Chronic hyperemia, the usual precursor of active inflammation, may be due to many causes, such as uterine malposition, excessive sexual stimulation, constipation, constitutional diseases such as anemia and obesity, and occupational conditions which necessitate prolonged standing and walking. The physiologically increased function coincident with pregnancy and its termination, the vascular changes, pressure, stretching and tearing, constitute the most common etiological factors.

Tuberculous inflammation of the cervix, according to Frank, constitutes about eight per cent. of all genital tuberculosis; primary tuberculosis is rare indeed. Most commonly appearing in the form of yellow-gray undermined ulcers about the external os, the diagnosis is confirmed by the evidence of the disease elsewhere, section examination of the ulcer tissue, and the identification of the tubercle bacillus.

Syphilitic inflammation of the cervix may show lesions of any stage, in the form of chancre, macule, patch, ulcer or gumma. The diagnosis of primary and secondary lesions is confirmed by demonstrating the presence of Spirochetæ pallidæ in dark field examination and the Wassermann test is of the greatest value in the secondary and tertiary forms. These specific diseases, however, are comparatively rare and offer little in the way of local treatment.

The relative frequency of gonorrheal infection is indeed hard to determine. Clinically and objectively the nature and course of chronic gonorrheal disease of the cervix is similar to that caused by other organisms and the diagnosis of such can be said to be authentic only when the presence of the diplococcus of Neisser can be identified in the discharge or in the cervical tissue itself. In the light of our presentday knowledge it is apparent that the prevalence of gonorrheal cervicitis has been overestimated and it seems fair to assert that the larger percentage of cervical infections is not gonorrheal, but more commonly due to organisms that inhabit the vagina normally, the staphylococcus, bacterium coli, and others; and of course it is easy for the streptococcus to gain access to the cervical cells. The treatment of gonorrheal cervicitis, except in its acute stage, is the same as advocated for cervical disease of other origin. In the acute stage proper treatment is rest, topical application of bland germicidal agents and frequent use of mildly astringent antiseptic douches.

It is the most common form of cervical inflammation, the ordinary eroded, hyperemic, cystic, hypertrophied type usually designated by the term endocervicitis, which is the chief interest of this paper. It seems at times difficult to demonstrate an absolutely healthy cervix in a woman subjected to careful gynecological examination. In nulliparous women a common finding is a normal appearing cervix with history and signs of a most profuse secretion of thick, viscid, mucinous discharge which is often most difficult to eradicate. Here we have a chronically hyperemic endocervix with the attendant hyperfunction of the cervical glands. Yet even in these apparently noninfective types it is fair to assume that some of the low grade organisms or floræ that inhabit the vagina have already gained access to the tubules of the Nabothian glands.

The cervix of the woman who has borne children is, however, the one most subject to serious disease. Even in easy normal labor, the cervix is traumatized more than any other part of the genital tract. The enormous amount of pressure and the degree of tension put upon its structure, must necessarily cause solution of continuity of some of its component parts, extravasation of blood, necrosis and replacement fibrosis of a more or less influential amount. To Sturmdorf we owe a great deal for having emphasized the relative unimportance of the laceration and the paramount significance of the superimposed infection. Fairly it can be said that laceration of the cervix of itself does not produce symptoms except the immediate ones, such as hemorrhage or shock, dependent upon its location and extent. During the stage of healing, however, due to many incidental circumstances, bacterial invasion is easy and likely. Throughout the postpartum period of involution the process of cervical repair is slow, the circulation is retarded, the mucosa is macerated and eroded, and the cell resistance to infection is lowered.

When one considers that the normal vagina is not sterile, it is not difficult to appreciate the ease with which the normal bactericidal power of the lower genital canal may be overcome and opposition be converted into invitation to active bacterial culture. Yet it is hard to isolate and identify the specific organism, due to the likelihood of mixed infection.

Pathologically the changes are most varied. In the mild form we have a chronically hyperemic cervix with glandular hyperplasia, exudation, hypersecretion, without infection. This type is usually found in the unmarried nulliparous woman; is often associated with malposition of the uterus and the discharge is viscid, glairy, and mucinoid. In the most severe form we find vascular changes, leucocytic and lymphocytic infiltration, edema, stroma reaction, glandular hyperplasia and general structural hypertrophy. The discharge is white or yellow, mucopurulent, with or without odor. Grossly the cervix is congested, intensely reddened or even cyanotic; the enlargement is apparent, the edema suggested by the evident glistening tensity of the mucous membrane. It is likely to be of varied color, spotted here and there with blue, yellow or white; irregular in consistency, hard and soft with excrescences apparent denoting retention cysts of the glands of Naboth in various stages of infection and degeneration. Varicosities may stud the surface. The size of the cervix may exceed that of the fundus, the enlargement being most marked in the vaginal portion.

But we must bear in mind that in the advanced stage of cervical inflammation we find a true cellulitis of all the structure, which spreads by contiguity of tissue, lymphatic extension and blood stream transportation. As a focal infection its importance must be recognized; its relation to arthritic and neuritic conditions has been frequently demonstrated. The portal of entry that a bad cervix offers to serious infection of the urinary system, pyelitis and pyelonephritis, is evident. It seems likely that extension to the tubes and ovaries is easy and often rapid. The adnexal pathology may be in the nature of a peritubal or periovarian inflammation or may easily become a suppurative salpingitis or oophoritis. It is not uncommon in the treatment of cervical disease to observe the rapid progress of the inflammation through the muscle tissue of the uterus itself, through the parametrium, finally localizing in a tube or ovary. And it is not uncommon to observe the spontaneous cure of such adnexal disease, aided by conservative palliative treatment.

Needless to say the most common symptom of cervical inflammation is leucorrhea. Then come in variable order dysmenorrhea, backache, bearing down pain in the lower abdomen, feeling of heaviness in the pubic region, headache. Menorrhagia or even metrorrhagia may be present. Sterility is a frequent complaint and the rôle played by cervical disease in its causation is evidenced by the frequency with which conception follows the cure of cervicitis.

The diagnosis is made by inspection, palpation and bacteriological examination. The appearance of the cervix is pathognomonic yet it is characteristic of cervical inflammation that even in cases where subjective pain is not present, careful examination will elicit the fact that even slight pressure upon, or movement of, the cervix is attended with pain of varying degree. In advanced disease, the cervix becomes fixed by the inflammatory exudate and induration extending into the parametrial tissue in all directions. The uterosacral ligaments become painfully rigid and backache from the lymphangitis here present is often of the most severe intensity. This fixity of the pelvic basin often responds quickly to proper treatment, with establishment of complete resolution in the structural anatomy involved. In the lateral fornices the indefinite tender thickening in the broad ligaments may occasion the diagnosis of salpingitis. The progressive course of cervical disease brings about tubal and ovarian involvement with the consequent organic and functional destruction.

The knowledge of the course and liability of cervical disease demands more care, first in its prevention and secondly in its eradication by proper therapeutics. It is probable that in the proper prophylaxis and treatment of inflammatory disease of the uterine cervix we have the greatest ability to lessen the incidence of cervical cancer. Our great duty is consistent with the opportunity for prevention. The care of the postpregnant woman has not received the attention that it has deserved. Postpartum examination and treatment should properly extend over a period of at least six months. It is not infrequent that a uterus that is apparently involuting well in good position at the end of one month, is large, boggy, subinvoluted and in extreme retroposition at the end of the third month. Lynch has estimated the prevalence of postpartum retroversion of the uterus at more than forty-one per cent. The best single prophylactic measure is the routine insertion at about the end of the fourth week, of a proper retroversion pessary which should be worn for at least two months. It must be borne in mind that involution is a physiological process that applies properly to all the reproductive anatomical structure; and any means that can be employed to hasten that reconstructive completion is to be greatly desired. Systemic hygiene enhances all local treatment. Many a well performed suspension operation is jeopardized by improper handling of a subsequent pregnancy. The physiological and functional hypertrophy of all the supporting structures that are an integral part of the phenomenon of uterine pregnancy may assure the permanency of an operative technic that otherwise might be transient. This is made possible by treatment essential to properly progressive involution and restored tonicity of the uterine supporting structures. Proper support assures better circulation, prevents strain and stretching. It not infrequently happens that a movable retroversion of the uterus is spontaneously cured by pregnancy and proper aftercare. Postural treatment, exercise, laxative diet, and local treatment are of value.

Successful treatment of cervical inflammation demands a thorough appreciation of the etiological and contributing factors in each individual case. General measures directed toward constitutional improvement are imperative. Locally the remedies used are legion. It will suffice here to mention briefly a few. Topical applications such as silver nitrate ten to fifty per cent., tincture of iodine, argyrol, mercurochrome, acriflavine are all useful in certain stages and types of cervical disease. Scarification, tamponing, astringent douches are of value. Intermit-

tent suction hyperemia and aspiration may be employed to advantage. The application of caustic potash as advocated by Strobell has undoubtedly effected many cures. Diathermy, endothermy and fulguration have their indications. Lactic acid and Bulgarian bacillus cultures are credited with beneficial effect. Radium, sponsored by Curtis, is drastic, not without decided risk, especially in regard to menstruation and subsequent pregnancy.

However, the agent par excellence in local treatment is the electrocautery. Actual cauterization of the cervix is probably one of the oldest therapeutic measures recorded. Hunner and Dickinson have more recently endorsed its value. Though technic may differ the underlying principle is the same; drainage of infective foci, destruction of bacteria, diminution of glandular cell hyperplasia and the consequent decrease in secretory matter. Multiple puncture with a fine electrode at red heat, to a depth of one half inch or more of the cystic follicles about the external os, with dilatation of the cervical canal and careful cauterization of the endocervical mucosa up to the region of the internal os, can be done in such a manner as to allow of marked regeneration of squamous epithelium and stroma cells from islets here and there. The glandular hyperplasia is obliterated, squamous cells replacing the glandular epithelium. There is a minimum destruction of muscle or fibrous tissue cells, with lessened stroma reaction and diminished vascularity. It has been found beneficial to apply to the cauterized area a solution of iodine in mineral oil. This has the germicidal action of the iodine without any evident irritation of the vaginal mucosa, and the oil exerts a soothing influence on the burned tissue. Cauterization may be done at intervals of seven to ten days with daily hot douching of bicarbonate of soda solution. The discharge after cautery application is extremely acid and prone to cause a dermatitis about the vulva that is best prevented by the alkaline douche.

Ordinarily no anesthesia is required, but in nervous women or women with sensitive cervices, infiltration with one per cent. novocaine, of each broad ligament at its cervical insertion, will afford complete analgesia. The course is necessarily slow extending in most cases over a period of several weeks, but the improvement is usually immediate and progresses often to complete cure. Atresia and stenosis of the cervical canal, conditions which are not infrequent sequelæ of the gross cautery under general anesthesia, with large electrodes occasioning destruction of considerable tissue *en masse,* and subsequent cicatrization, do not occur. Proper cauterization will restore a diseased cervix to its normal healthy condition.

Logically, the ideal indication for active cauterization is found when the cervical disease is *per se* the dominant pathological condition. If there exists bad laceration of the pelvic floor or of the cervix itself, malposition of the uterus, genital neoplasm or adnexal disease, then cauterization of the cervix is contraindicated, except in certain cases as a palliative, preoperative preparation.

Treatment of cervical disease by cauterization yields such brilliant results that it is seldom necessary to resort to surgical means. In fact it is fair to say that proper treatment by cautery gives better results than can be obtained by surgical technic, except where extensive laceration and dystocia exist.

The operation of choice is the operation that will, depending upon the age and condition of the patient, best remove the diseased tissue and conserve the function of the cervix. Schroeder's technic, modified to suit the severity of the individual case, offers the greatest expectation of permanent cure with minimum impairment of function. And this is so because in this method, one can split the cervix, outline the extent of involvement, remove as much or as little tissue as is necessary, and secure better approximation of endocervix and vaginal mucosa, and better hemostasis, than is possible with any other technic. Interrupted figure of eight sutures of chromic catgut are used throughout. Because of these facts, cicatrization, stenosis or atresia of the cervical canal, does not result.

In conclusion, it may be well to reiterate a plea for better care of the postpregnant woman; for better prophylaxis of cervical inflammation, the precursor of cervical cancer; to commend the conservative treatment of this disease and to discourage the mutilation of the cervix uteri by ruthless surgery.

The Rubin Test and Its Modifications in Female Sterility

ADOLPH JACOBY, M.D.
New York

Sterility in the female still provides a fertile field for discussion, and offers unlimited opportunity for further progress, and yet it may be safely said that in this condition one of the outstanding advances in gynecology has been made. Excluding all those cases directly due to the male, and also those cases in the female with palpable pathological lesions of the adnexa, or other gross pathological changes evidently responsible for the sterility, there still remains a large group of cases to be accounted for. It is in this group that progress in more accurate diagnosis has taken place. A part of this group are those cases in which there is some endocrine disturbance as the basis of the sterility, another part may be the result of subfertility, due to faulty diet or other metabolic disturbance, leading to a state of relative sterility. The other cases in this group are due to occlusion of the lumen of the tubes, and have heretofore been unrecognized without resorting to operation. It is in detecting this group that the Rubin test has found its greatest applicability.

The test first introduced by Rubin in 1920 determines the patency of the tubes by the ability to pass gas through their lumina into the peritoneal cavity.

For this purpose the Rubin technic requires a tank of carbon dioxide gas with an attached pressure reducing gauge, to reduce the pressure of the gas as it comes from the tank; a flow volumeter to measure the quantity of gas introduced; a spring or mercury manometer to measure the pressure at which the gas is passed through the tubes; a Keyes Ultzman cannula specially prepared by boring extra holes near the end, and slipping a rubber urethral tip about 1.5 inches along the shaft to act as an obturator; the rubber tubing necessary to connect up these parts; a stop cock to control the flow of gas; a tenaculum and a bivalve speculum.

Furniss has modified this technic by filling a syringe with gas from the tank and injecting this through the cannula. I have further modified this procedure by doing away with the tank of carbon dioxide and its attachments, and substituting a Janet Frank syringe of 150 c.c. capacity, and injecting atmospheric air. The advantages of this modification are obvious. It eliminates the cumbersome tanks of gas, at the same time permitting accurate measurement of the amount of air introduced. There is no possibility of running short of gas during a test. The apparatus is portable and inexpensive to operate.

The technic used in performing the test is as follows. The patient is placed in the dorsal position. A bivalve speculum is introduced. The cervix and vault of the vagina are painted with tincture of iodine. The cannula is introduced into the cervical canal past the internal os, the rubber tip on the cannula pressing against the external os and acting as an obturator. The cannula is connected by rubber tubing and T tube to the manometer on the one arm and a Janet Frank syringe with the plunger drawn out to its fullest extent on the other. Air is gently introduced by pressure on the plunger. The pressure exerted is recorded on the manometer. Fifty c.c. of air are introduced. If the tubes are closed the pressure steadily rises and no air enters. This rise is permitted until a pressure of 220 mm. of mercury is reached. Above this it is dangerous to go, as rupture of the tubes and hemorrhage may occur. If the tubes are open the pressure at first rises anywhere from 60 to 120 mm. and then falls as soon as the initial resistance is overcome, and the air begins entering the peritoneal cavity. With the tubes partially obstructed the initial pressure may rise to 160 mm. or over before dropping and admitting air and then may fall only slightly.

There is no immediate reaction following the entrance of air into the peritoneal cavity. From five to fifteen minutes after assuming the upright position, the patient complains of pain usually in the right shoulder, less frequently in the left or both, and sometimes in the upper abdomen. The pain persists for from one half to twenty-four hours. X ray or fluoroscopy will reveal the layer of gas under the diaphragm. This is not essential for diagnosis, because if it is certain that there is no leak in the apparatus, there being no regurgitation past the cervix, and the manometer indicates a free flow of air, and subsequently the patient complains of the characteristic shoulder pains, the air must have entered the peritoneal cavity through the tubes. There is no other place for it to go.

In the event that no air flows at a pressure of 220 mm. maintained for several minutes, the test is considered negative and the closure of the tubes presumed. This is, however, not conclusive. The test should be repeated at one or two week intervals. No tubes should be regarded as absolutely occluded unless at least three tests have been made and all have proved negative. There are repeated instances in which the test has been negative on the first trial, and on subsequent examination has become positive. These cases are usually due to a temporary kinking of the tubes or plugging by inspissated mucus or slight exudate or swelling of the mucosa, or velamentous adhesions closing the fimbriated extremity, which conditions are overcome by the air introduced under pressure.

No ill effects have been observed following the test. Air embolism has not occurred, nor has there been any infection as the result of the test. The test of course should not be performed in the presence of a purulent cervical discharge, nor when the tubes are distinctly enlarged. It is best not to test tubal patency just before or following menstruation nor when there is an undiagnosed period of amenorrhoea present.

The test undoubtedly finds its greatest applicability in the diagnosis of tubal patency in sterility. There are however a number of other conditions in which it may be used to advantage. One of these is the production of pneumoperitoneum for pelvic and abdominal x ray diagnosis. In this procedure about one thousand cc. of oxygen or carbon dioxide are used, followed by immediate x ray examination. Another use for the test is for the determination of subsequent patency of the tubes after a salpingostomy has been performed, as well as to maintain the patency of the artificially opened tubes. Still another indication for the test is in the determination of the success and permanency of artificial sterilization when this is done by the resection of a portion of the tubes. The test may serve further to determine whether, in some cases following myomectomy done with a thought to possible future pregnancy, the uterine ostium of the tubes has been occluded by the suture of the bed of the fibroid following its removal. A further interpretation of the information derived from the test, though in the nature of a deduction, is yet of the greatest importance. The test determines patency of the genital tract beyond all question, and when once established, stenosis in any part of the tract can be excluded as a cause of sterility. This consequently contraindicates any operation or other manipulation for the purpose of straightening the uterine canal, or dilatation to overcome the supposed stenosis.

The results obtained from the use of this test in sterility have been enlightening and highly instructive. From an analysis of my own cases and those reported in the literature, it appears that in about thirty-three per cent. of cases sterility is due to closure of the tubes. Many of the cases negative at the first examination subsequently became positive. Several subjects became pregnant following the establishment of patency. It is not advisable, however, to attempt to use the test as a therapeutic measure to establish patency in closed tubes. That there was so large a percentage of cases due to nonpatent tubes,

seems to show that many of these have heretofore been attributed to other causes. In the light of our present knowledge it is imperative that no therapeutic procedure shall be instituted in the treatment of female sterility, until postcoital examinations for spermatozoa from specimens taken from the vaginal, cervical, and uterine secretions have been made, and a transuterine insufflation of the tubes to determine their patency has been performed.

Pregnancy With Complications

Hyperemesis Gravidarum; Varicose Veins; Hemorrhoids; Left Inguinal Hernia; Threatened Eclampsia; Occiput Posterior Position; Podalic Version

DANIEL H. BESSESEN, M.D.
Minneapolis, Minn.

Case.—The patient, a tertiagravida, para 4, aged twenty-nine, consulted me in the third month of pregnancy for pernicious vomiting. Her history revealed numerous attacks of sore throat and arthritis, tonsillectomy, appendectomy, and three easy deliveries of well developed babies. The last period had commenced on February 16, 1923. Physical examination showed a left inguinal hernia, varicose veins, hemorrhoids and a three months' pregnancy. She was treated, as usual, with ovarian extract three grains intravenously daily for four days and five three times a day by mouth for a month, with three grams of sodium bromide by rectum every four hours and rest in bed.

The vomiting was quickly checked, and she continued without complaint until the sixth month. At this time she had a uterus the size of a nine months' pregnancy and was afflicted with spots in front of the eyes and a queer loss of sensation over one side of the body with dizziness. The blood pressure was 130/90 and the urine contained only a faint trace of albumin with no casts. Rigid diet was prescribed, together with rest and chloral hydrate. The blood pressure dropped to 100/60. Two weeks later she complained of pains in the throat and muscles, which indicated an infection of some sort, though no fever was present. Calcium lactate in one gram doses was given three times a day over a period of one week. Her spells of weakness and dizziness and numbness continued for approximately six weeks, when she was able to be a little more active with greater comfort. During this time the stomach gave much trouble and constipation was quite marked. The uterus apparently did not increase much in size during the last six weeks of pregnancy. On November 16, 1924, at 2 a. m., severe pains started and at 5 a. m. there was three fingers dilatation. At 6:30 a. m. examination showed that dilatation was complete but the head was caught transverse in the pelvis, occiput slightly posterior, wedged tightly against the symphysis so that progress was delayed. Forceps were attempted but because of the insufficient space to place the blades in the axis of the child's head version was performed. Both mother and child recuperated satisfactorily.

Vomiting of pregnancy is considered to be the reresult of ovarian insufficiency and hyperirritability of the nervous system. The administration of ovarian extract alone is frequently sufficient to check the vomiting. When emesis becomes pernicious, depressants are adjuvants. When acidosis is present, the intravenous administration of glucose solution with possibly a small dose of insulin in addition to the foregoing will give the most prompt relief. This patient had vomited all food for four days and all fluids for two days when first seen.

Varicose veins should be treated expectantly until after delivery when, if necessary, they may be treated surgically. They frequently disappear after the abdominal tumor has been relieved.

The hemorrhoids were increasingly troublesome during gestation and continued somewhat so after delivery. As with the varicose veins of the legs they are best operated upon after delivery.

Hernia with pregnancy unless of unusually severe nature or unless the patient lives in an isolated place where ready medical aid is not at hand, does not require surgical repair until after delivery. In this case, the hernia was more noticeable during the last trimester but caused no trouble during delivery.

The dizziness and numbness were undoubtedly due to the presence of infection in the body. This patient had had frequent attacks of arthritis previously. The large size of the uterus with its interference to elimination and digestion and pressure on the liver predisposes to eclampsia. In the presence of infection this state becomes almost a certainty. The treatment of infection with forced catharsis and rest aids in averting such a danger.

In this patient it might be questioned whether the symptoms were due to a threatened eclamptic state. The hernia might probably have given the same picture. No case has been reported, apparently, of hyperemesis gravidarum and eclampsia or threatened eclampsia occurring in the same patient. The underlying pathology is reputed to be at variance. But in this case, the presence of the very large uterus, the symptoms of slight kidney injury make the brain disturbance appear preeclamptic.

The position of the head was practically that of occipital posterior, and the force of the pressure against the symphysis caused extreme pain in the urethra. This pain is characteristic when the progress of labor is delayed at this point. The head was wedged tightly against the symphysis in front and the sacrum in back and pushing the head up and applying forceps did not facilitate matters. A version was the simplest procedure under the circumstances.

Historical Medicine

The Early Years of the New York Post-Graduate Medical School and Hospital*

HENRY DWIGHT CHAPIN, M.D.
New York

In order to have a clear conception of the conditions underlying any social movement, it is necessary to study the background existing before and during such a movement. With this in mind, a brief glance at the status of medical education at the time the Post-Graduate Medical School was founded may be of interest.

Medical teaching was then carried on exclusively by schools of low or mediocre standing grouped principally in the larger cities of the country. These institutions were practically proprietary schools although a few had university connections that, however, were only nominal. No preliminary examination for entrance was required and the same lectures, comprising the various branches of medicine, were repeated each term and after two years thus spent the student could come up for examination for the M.D. degree. This conferred the license to practise medicine, and, although clinics were held, attendance was not compulsory; it was hence quite possible for a student to be authorized to begin the practice of medicine without ever having seen a sick person. This deplorable state of affairs was remedied not by inauguration of the medical colleges but by outside influences. I believe the action of the State Board of Health of Illinois in requiring a state license to practise medicine was one of the earliest factors in raising the standard of medical education in this country. Other states gradually followed so that soon a state examination was everywhere required before allowing a candidate to practise medicine. This naturally caused the colleges to raise their standards as the degree of doctor of medicine which was conferred by them was no longer a license to practise as heretofore.

DR. D. B. ST. JOHN ROOSA

At the time the Post-Graduate Medical School was founded short courses and insufficient clinical instruction thus characterized the operation of the undergraduate schools. If these courses were defective even in training beginners, what shall be said of inviting graduate physicians to sit on the benches to try and brush up by attending clinics intended only for undergraduates? Yet this was all the great city of New York, with its enormous wealth of clinical material, had to offer physicians who wished to keep up to date in medicine or to pursue advanced studies.

At this time a man of strong character and broad vision, Dr. D. B. St. John Roosa, resolved to remedy the condition. He was then a clinical professor at the Medical School of New York University. With some of his colleagues in the faculty, he requested the university authorities to form a postgraduate faculty that would specialize in advanced instruction and demonstration adapted for physicians only. This was refused and as a result Dr. Roosa, Dr. W. A. Hammond, Dr. J. L. Little, Dr. Piffard, Dr. Pallen and Dr. Sturgis resigned from the Faculty.

After some further agitation and discussion it was resolved to hold a large public meeting to consider the possibility of starting a new college to be devoted exclusively to postgraduate instruction. This meeting was held in the summer of 1882 at Chickering Hall, a large auditorium then situated on lower Fifth Avenue. Several enthusiastic speeches were made by prominent physicians and laymen and the new enterprise was launched.

The first clinic was held by Dr. Little on November 6, 1882, in the lecture room of the College of Pharmacy, then located on Twenty-third Street east of Third Avenue. This building continued to be used for teaching, while the ground floor of a tenement house next door was utilized for dispensary purposes. The critics of the undertaking took pleasure at this time in speaking of the medical school in a tenement house.

In 1883, a large building on Twentieth Street, formerly used as an old ladies' home was purchased and the institution moved to that location. The purchase was effected by bonds furnished by the Faculty toward payment. The bonds were later turned in by the holders and publicly burned.

The building was at first used only for teaching and housing the dispensary. A little later, in 1884, a few private rooms in the building were rented by some members of the Faculty for the use of their patients and this really constituted the beginning of the hospital. The appliances were crude and the food was furnished by a Third Avenue restaurant. In 1885 a hospital association was formed independent of the school which continued for about a year.

*Address delivered at the opening of the McKernan addition to the Post-Graduate Hospital, January 22, 1925.

Fig. 1.—First hospital; formerly an old ladies' home.

A little later this association was abolished and the school and hospital were amalgamated.

It was hard work to finance and operate the school and hospital but Dr. Roosa was loyally supported by the Faculty. Dr. Clarence Rice and Dr. Samuel Lloyd were especially active in working for the support of the school at this time.

As students came in large numbers from all parts of the country to take the courses, it soon became evident that this plant was inadequate to be transformed into a large teaching hospital. Another great effort was accordingly made and in 1889 the plot on the corner of Second Avenue and Twentieth Street was purchased. Construction was started—largely on faith—but soon a great misfortune was literally unearthed. In digging the foundation an underground stream was brought to light that required a very large sum to properly deflect. The contractor failed and the work was held up indefinitely with unpaid bills pouring in on the directors.

At this time, when the outlook was darkest, the ladies committee of the babies' wards under the leadership of Miss Ella Russell began to raise money as their share in the expense of building and equipping the wards in the new building. Some generous sums were thus contributed at this critical time and construction was resumed. It is doubtful if the undertaking would have survived without this timely aid.

Fig. 2.—The hospital at Second Avenue and Twentieth Street.

The new building when completed represented at the time a modern hospital equipment well suited to caring for the sick as well as for teaching physicians the newer advances in medicine.

On a pleasant day in June, 1891, a procession headed by Dr. Roosa and Dr. Lloyd marched from the old to the new building and took possession.

Thus ended and began a new era in postgraduate medical instruction. It is doubtful if there has ever been a more unselfish group of physicians than those who then labored without return of any kind to place the institution on a firm footing. There was a heavy debt on the property and second mortgage bonds were taken by these physicians and their friends to help out. At one time over $40,000.00 was subscribed by the Faculty to pay a floating indebtedness and even these bonds were afterwards all turned in. A few of our doctors were even willing to endorse notes, thus risking what little they possessed in order to meet the growing deficits and keep the enterprise growing. Thus the faith and sacrifices of a few devoted physicians were directly responsible for the inception and early continuance of an institution for the benefit of the medical profession and through them of the public at large.

The success attending the teaching was evidenced by the increasing numbers of students matriculating at the school. Although some mistakes in personnel were made, as in all institutions, there was a group of brilliant clinical teachers at this time rarely equalled and not surpassed anywhere in the country. Among these earlier teachers it is only necessary to recall such names as Dana, Abbe, Bache, Emmet, Bangs, the Hammonds, C. C. Lee, Satterthwaite, Hanks, Powell, Phelps, Phillips, Rice, Porter, Lloyd, Caillé, Einhorn, Willy Meyer, McPhee, McKernon, and others of like calibre. One can thus appreciate what was offered in the line of instruction at that time. The reputation then built by the teaching of these men has stood the institution in good stead until the present day. The demonstration that physicians need a particular type of instruction especially fitted to their needs and a different kind of teacher than is found in undergraduate institutions was early proved in this school.

In other ways the hospital forged ahead and took its place among the leading institutions of the country, quick to recognize and apply any advances in scientific or philanthropic effort. Two examples of this may suffice. Shortly after Roentgen's great discovery, Dr. Lloyd went to Europe to secure the necessary material and data. As a result, in 1895 the first x ray machine was installed in the hospital, antedating its use in other hospitals.

On the philanthropic side, hospital social service was started in the children's division of the hospital as early as 1890. As far as I know, this was the first actual and continuous operation of this beneficent work anywhere undertaken. It was based on

ne idea that in possibilities of service the hospital epresents one of the broadest human institutions. he treatment of disease, teaching and research ould all be combined in its operation. With refer- nce to the latter, not only the investigation of the uses and treatment of individual diseases but social isorders and maladjustments should likewise be onsidered. To attain its broadest usefulness, the ospital must serve as a sort of social laboratory which disease and distress should be traced to eir ultimate sources. Only thus can relief be made ermanent and recurrence of disease prevented.

Acting on this idea, an intensive study of the life onditions of 3700 sick children treated in the hos- ital was made, starting in 1900 and continuing rough a series of years. As the result of this udy the real underlying causes of these sicknesses ere explained along three broad lines—insufficient arnings, bad housing, and ignorance on the part of ne parents.

While these and other efforts were constantly be- g made, in addition to the routine of teaching, Dr. oosa and his colleagues were meeting numberless ifficulties and obstacles in guiding the development nd growth of the institution. The greatest source f anxiety was on the financial side. There was lso criticism and obstruction that were very trying o one who was wearing out his life on one of the ressing problems of the day—that of diffusing and idening the products of advanced medical education o as to reach the profession at large and at work.

Nothing could daunt the faith of Dr. Roosa in the uture of postgraduate medical instruction. In the arkest hours, when failure seemed imminent and navoidable, he never doubted that success would ventually come. He took the long view and had ide faith, high hope and abundant vision.

But years of anxiety and persistent toil finally old on him and the leader passed on. Often in the ffairs and struggles of life we delay our meed of raise too long. When tired hands are folded, we our into ears that cannot hear our appreciation of reat efforts and sacrifices. At least Dr. Roosa lived o see the foundations firm and the future hopeful. We can well apply to him those ringing lines of Kipling—

> And only the Master shall praise us, and only the Master shall blame,
> And no one shall work for money, and no one shall work for fame,
> But each for the joy of working, and each in his separate star,
> Shall draw the Thing as he sees it for the God of Things as they are.

So much for the past. What of the future? It s a far cry from the humble beginnings to the arge and complete plant that now houses the Med- cal School and Hospital, but I believe that post- raduate medical instruction will develop along still arger lines. New York with its vast cosmopolitan opulation should become the recognized medical cen- er not only of this country but of the world. Such ttainment will call for vision, courage and action— nd the leaders must lead.

It is true that the undergraduate colleges are now iving their students a broad training, although ome think the laboratory is being overstressed in

Fig. 3.—The hospital with large addition which was erected by the Hewett legacy.

comparison with wide clinical teaching and experience.

In the past few decades, however, scientific medicine has made greater advances than in the whole preceding period of history. There is every reason to believe that the coming years will present even greater discoveries and advances. How can the busy physician keep up with these rapid changes except by frequent visits to a great teaching hospital where every improvement in diagnosis and treatment can be demonstrated. Here lies the great future necessity of postgraduate medical instruction. The courses should be long and short to accommodate both the specialist and the general practitioner.

A university connection would greatly help in developing some of these courses and in training young men as teachers. It would offer a splendid field for such training as it must always be remembered that this school was founded primarily as a teaching institution and the hospital is to be utilized for demonstration. The early history of this school and

Fig. 4.—The hospital with the McKernan addition, taking in the Second Avenue block.

hospital developed some great and unselfish men who builded better than they knew. They form an inspiration for those who now and in the future carry on in this great work. As all give the best that is in them to build a great and lasting institution, we may well have faith that success will be assured.

At any rate, let us feel that we can apply to a these workers—past, present and to come, those fa miliar lines from Addison's *Cato:*

> 'Tis not in mortal to command success,
> But we'll do more, Sempronius,
> We'll deserve it.

51 West Fifty-first Street.

Contributors to the Science of Medicine

Vesalius, the Father of Anatomy

Until comparatively recent times little was known of Vesalius, the Father of Anatomy, the man who had the genius and patience to discover the facts of anatomy and the courage to force these facts on a medical profession permeated and held in thrall by the erroneous views of anatomy taught by Galen. Vesalius, inquisitive of the truth as all pioneers of genius are, was not content to accept the statements of Galen, but investigated from nature himself, and thereby revolutionized the knowledge of anatomy. According to Dr. James Moores Ball, of St. Louis, "The whole of anatomy is a study involving correct descriptions of the component parts of the body and accurate delineations thereof, may be said to have been founded by Andreas Vesalius and Jan Stephan van Calcar."

In the Renaissance which took place in Europe after a period of intellectual darkness lasting for almost ten centuries, medicine awoke from its lethargy and fell into step with the general advance of knowledge. Italy was the land in which this movement towards the light began. She took the torch from the Greeks and handed it on to the nations still sitting in the shadow of intellectual darkness. This revival of learning, be it understood, was from the seeds which had been planted during the Middle Ages but which had borne no fruit until the time had come for a seemingly "spontaneous outburst of intelligence." Intelligence had not been extinct but dormant. In every branch of human intellectual endeavor this outburst manifested itself—in art and sculpture, literature and philosophy, physics and geography, history and invention and in anatomy. Of course, some share in this revival must be ascribed to the recovery of the long lost writings and sculptures of ancient Greece and Rome. But it went deeper than this. It included all branches of learning.

In referring to the Renaissance and the discovery of anatomy, and the salient facts of its establishment on a sound basis, it may be pointed out that there was an alliance which was of reciprocal benefit between anatomists and great artists. Indeed in recent years more than one attempt has been made to show that it was not Vesalius, but Leonardo da Vinci that greatest genius of all ages, who was the founder of modern anatomy. It is true that if Leonardo's anatomical sketches had been published during his lifetime, they would have revolutionized anatomy. However, the conclusions of McMurrich in the *Medical Library and Historical Journal,* December, 190 quoted here, are an apt and fair presentation of th case. "Leonardo was the first to create a new ana omy, but he created it for himself alone; Vesaliu demonstrated a new anatomy to the world. It wa the publication of Vesalius's *Fabrica* that revolutio ized anatomy, while Leonardo's drawings were lyin unpublished, at first the cherished possessions of hi favorite pupil, Melzi, later in the Ambrosian Librar in Milan, and still later forgotten in the Roya Library at Windsor. We must credit Leonardo a being the forerunner of the new anatomy, but Vesa lius must be recognized as its founder."

In Italy during the Renaissance were the mos celebrated medical universities of the world. Th ancient universities of Padua, Bologna, Pavia, Pisa and Rome eclipsed the schools of Paris and Mont pelier, of Toulouse and Salamanca. The Italia cities were filled with students from foreign lands Padua had more than one thousand new student every year, salaries were paid to her one hundre professors, and medicine was looked upon as a nobl profession. It is worthy of notice that the anatomi cal knowledge of Galen, who up to the time of Vesa lius dominated the teaching of anatomy in the medi cal schools, was largely gained from the dissectio of the lower animals. Despite these limitations h possessed a remarkable familiarity with practica anatomy, while his knowledge of osteology was ex tensive. He made grave errors in some of his de ductions. When Salernum was the great medica school of the world, anatomy was taught from dis sections made on pigs.

Andreas Vesalius, or Wesalius, was born in Brus sels on December 31, 1514, doubtless of Flemish origin, as the name was adopted from Wesel o Vezel in the Duchy of Cleves, which his family claimed as their native place. Little is known o the youth of Vesalius. At an early age he was sen to the University of Louvain and it is said that when quite young he began the practical study of anatomy by dissecting the bodies of mice, moles, rats, dogs and cats. In 1933 the young Fleming went to Paris to obtain a medical education, as at that time Paris was the Mecca of the medical world, where Sylvius a hard and fast disciple of Galen, was a teacher of anatomy.

The teaching of anatomy in the early part of the

xteenth century was defective. There was too reat a blind belief in the views of Galen and theoriz-ng from his teaching, while of actual dissection little vas done. Even when a dissection was performed, comprised only a superficial study of the intestines nd abdominal muscles and the bones, veins, arteries, nd nerves were almost entirely passed over. It was ne lack of opportunity really to study anatomy vhich led Vesalius to endeavor to learn anatomy rom Nature. He dissected numerous dogs and ventually procured bones of executed criminals rom Montfançon where their bodies were deposited. Ie thus became a master of the osseous system. In 536 he returned to Louvain and late in this year r early in 1537 conducted the first public anatomy nat had been held in Louvain in eighteen years.

In 1837 Vesalius published his first book, *Parahrasis in nonum librum Rhazæ,* a free translation of he ninth book of the Almansorem of the celebrated Rhazes. In 1537 he first visited Italy. He went to Venice where the study of anatomy was not tabooed as was frequently the case at that period, rather it was encouraged. In Venice he met his countryman, Jan Stephan van Calcar, who was afterwards to collaborate with him in the production of his first anatomical plates.

ANDREAS VESALIUS

Vesalius, at about this time, settled in Padua, and on the sixth day of December, 1537, shortly after having received his degree as Doctor of Medicine, was appointed professor of surgery with the right to teach anatomy at the famous University of Padua. Soon after accepting the chair of anatomy in Padua, he articulated a human skeleton for use in his class room. He next prepared a set of anatomical plates. In 1542, after three years of most arduous work, Vesalius completed his marnum opus, the *Fabrica,* and twelve days later he wrote the last word of the *Epitome.* A fortune was spent upon the illustrations and publication of the great work. The first edition of the *Fabrica* is folio volume with magnificent illustrations on wood. It is not stated who drew the illustrations. They have been attributed to Titian. The great anatomist, however, speaks regretfully of the large sums which he was obliged to pay, in order to induce skilled artists to do this kind of work. When it is borne in mind that antiseptics and preserving fluids were not known, it is not surprising that great artists were averse to encountering the foul odors which emanated from cadavers which had been kept for some time. Dr. James Moores Ball concludes that the illustrations for the *Fabrica,* like the figures in the *Tabulæ Anatomicæ,* were made by Jan Stephan van Calcar, the favorite pupil of Titian. Van Calcar was a Fleming from the Duchy of Cleves.

The *Fabrica* is the rock on which the reputation of Vesalius firmly rests. It contains the rudiments of anthropology as well as the first illustrations of comparative anatomy. The first book is devoted to the bones and cartilages with which he deals, with a thoroughness and accuracy which both amazed and aroused the envy of his contemporaries. In it he corrected some errors made by Galen. The second book, which describes the ligaments and muscles, while hardly reaching the high standard of the first book, is superior to any work on the subject written before. The third book is given over to a description of the veins and arteries. This book is a great advance over previous works of a similar kind. Although he follows the traditional belief that the blood movement is a sort of flux and reflux in the veins, he overlooks the function of the venous valves, describing them as eminences or projections which in no way interfere with the flow of blood. The fourth book deals with the cerebral and spinal nerves, and the fifth with the organs of nutrition. The sixth book is taken up with an account of his views of the anatomy of the lungs and heart.

Vesalius knew that in various details the accepted physiology of the vascular system was wrong and he had more than an inkling of the truth. If he had lived a few years longer or if he had remained professor of anatomy in Padua instead of accepting the post of court physician to Charles II, it is likely that the circulation of the blood would have been discovered by him. That, however, was in the lap of the gods. Vesalius pointed the way, and Harvey, following the trail, made that epoch making discovery.

After the publication of the *Fabrica,* opposition to the views of Vesalius became increasingly bitter. Pioneers, or those who seek to upset long held views are invariably vigorously attacked by the conservative members of a profession who always greatly outnumber the searchers for and finders out of obscure problems. His old teacher in Paris, Sylvius, a hidebound follower of Galen, was one of the most prominent of his antagonists. The Padua Medical School itself was a very hotbed of opposition. It is said that weary of the seemingly hopeless task of convincing men of the truth, sick of futile arguments and disputations, Vesalius threw his manuscripts into the fire and bade a long farewell to science. It is while in this frame of mind that he accepted the post of court physician to Charles II of Spain, the greatest monarch of his time. Although Charles in 1555 abdicated in favor of his son Philip, Vesalius was retained as court physician.

In 1564 Vesalius left Madrid suddenly, after a stay of twenty years, during which time he had neglected science or rather perhaps because there was little opportunity to pursue its study. According to

one account, which in the opinion of Dr. Ball appears the most plausible, the reason that Vesalius left Madrid in such great haste, is told in a letter written January 1, 1565, to the physician Caspar Pencer by Herbert Languer, the Huguenot friend of Philip Sidney. This letter, after mentioning that Vesalius had died in Jerusalem, narrates why he went there. Believing a young Spanish nobleman whom he had attended to be dead, he obtained leave of the parents to open the body to attempt to find out the cause of death. This was granted, but he had no sooner made an incision than he perceived that life was not extinct. The parents coming to the knowledge of this were not satisfied with prosecuting him for murder, but denounced him to the Inquisition, hoping that he would be punished with greater rigor by the judges of that tribunal than by those of the common law. The King of Spain interposed, and saved him on condition that he should undertake a pilgrimage to the Holy Land. Whether this reason for going to Jerusalem is true or not—evidence is in favor of its truth—it is a fact that Vesalius returning from the Holy Land again to teach anatomy at Padua, was wrecked on the Island of Zakynthos, while crossing the Ionian Sea, where on October 15, 1564, he perished from exhaustion. The end was tragedy of the man who before he was thirty years old had revolutionized anatomy and is now recognized as the greatest anatomist who ever lived. Why the fame of Vesalius is not better known is largely because his writings were in Latin and were published before the sixteenth century.

This account of Vesalius is largely gathered from his life by Dr. James Moores Ball, of St. Louis.

Student Life at Glasgow University About Ninety Years Ago.—J. H. Alexander, M.B., C.M., writes (*Glasgow Medical Journal,* January, 1925) that most of the notes he has used as a basis for his article were narrated to him by his father, and are significant in showing how different was the curriculum in those days from what it is now. His father was William Alexander, M.D., born in 1815, the year of the battle of Waterloo. He received a pretty good basic education from the village schoolmaster, and made up his mind while still in school to become a doctor. In June, 1831, he entered the shop of a chemist of Kilmarnock, where he learned to make pills, powders, tinctures, etc., and how to read prescriptions and to dispense medicines. In November of the same year he entered as a student of medicine at the old University at Glasgow, and took up the study of anatomy, chemistry and surgery. In the chemistry class, among the subjects taught were electricity, galvanism, and steam. "The students were shown many experiments with galvanic batteries, and as to steam, the professor had a small locomotive, with a charcoal fire boiler, which was shown running to demonstrate the power of steam." William used to travel to and from Glasgow from Kilmarnock by stage coach, a journey requiring nearly three hours. In February, 1832, the epidemic of cholera which had been raging on the Continent appeared in Scotland. The first case in Glasgow lived in the apartment above William's. The patient was a man who died after a few hours' illness. William was not frightened and continued h studies.

Great precautions, or what were then considere such, were taken in all the towns and villages; n body was permitted to enter or depart if it we known that he or she had come from a cholera i fected district; thus the influence of carriers' spread ing the disease was recognized. By order of th magistrates, on the main roads leading into town and villages, were stationed men called "Buff-the Beggars" who were instructed not to allow any pe son to pass unless they were certain that he or sh had not come from a cholera infected district, an on no account to allow vagrants and beggars to pas at all; beggars were marched to the boundary of th borough, setting them on their way to Glasgow o elsewhere, and giving them a parting buff as the left; hence the name "Buff-the-Beggars." By Apri cholera was raging so fiercely that William's par ents wrote frequently begging him to come home but he refused. At last, however, he yielded to thei entreaties, and went, carrying with him a chemica retort and a couple of lancets. That summer he tool Sir William Hooker's botany classes, and the fol lowing session classes in anatomy, practical anatomy surgery, clinical surgery, materia medica, and mid wifery.

To supply the dissecting rooms in Glasgow, Edin burgh and Aberdeen, bodies recently buried were taken out of their graves by the socalled Resurrec tionists. Although the risk was great from possible discovery from watching relatives in the graveyard the price paid for the bodies was a high one and made the venture worth while in view of the grave robbers. The bodies of criminals who had under gone capital punishment were always sent to the anatomical rooms. It was not very difficult to get bodies, for capital punishment was visited on mur derers, sheep thieves, forgers, and coiners of base money. Sometimes experiments were made on the bodies of newly hanged persons. The body would be taken to the dissecting room almost the moment the hanging was completed, and the batteries applied, with often very uncanny results.

At that time all operations were performed without anesthetics, for chloroform and ether were unknown. Antiseptic dressings of wounds were also unknown. "The groans and cries of patients undergoing operations were pitiful to hear; the shock to the system was very great. Blood poisoning was a frequent ending to operations; secondary hemorrhage often took place, erysipelas and hospital gangrene would spread from one surgical case to another. Owing to the almost absolute fatality which followed them cranial and abdominal operations were prohibited."

The stethoscope invented by Laennec was seldom used; it was then a large, clumsy wooden affair regarded more as a toy than as a useful instrument. Sounding was performed by direct application of the ear to the patient's chest, with a towel between. In the fever wards were often cases of diphtheria, smallpox, typhus and scarlet fever. The professor received in his private room the class fees from students. As educational equipment the students had not much more than a blackboard and some chalk. There were almost no laboratories, and the microscope was not used in physiology or medicine. With

the exception of acquaintances in the classroom, there was little opportunity for contact with other students. William studied, except on Saturdays and Sundays, eight hours a day.

In 1834 he decided to present himself for the degree of Master in Surgery. There were then no written or practical examinations; only oral ones. William was examined at one and the same time on all the subjects he had studied. One of his questions was: "In what respects does lithotomy of the moderns differ from lithotomy of the ancients?" He was asked to translate some Latin at sight, from a book he had studied, however. When the examination was over and he was leaving the room, one of the examiners told him to wait. He was soon told that he had passed satisfactorily, and that in a few days he would receive his degree of M.C. William was nineteen years old when he received this degree.

During the next session he took courses to enable him to qualify for his degree of M.D. and studied in some of the Paris hospitals. In 1836 he presented himself at Glasgow University for his examination, which was a very severe one lasting nearly two hours, and including about 180 questions, the translation of three pages of Latin, and the writing of a short essay on diabetes. Both diplomas were given to him in tin boxes with enormous red wax seals several inches long.

Antique Microscopes.—The celebrated collection of antique microscopes, made by the late Sir Francis Crisp, was sold at auction on February 17th. Among the 371 lots in the catalogue, says the *British Medical Journal,* February 14, 1925, there are many of great interest for their historical associations, their excellence of workmanship, or the beauty of quaintness of their design. In the seventeenth and the first half of the eighteenth centuries microscopes were not the severely practical utilitarian instruments with which we are familiar. The craftsman was not content with having done his best to turn out an optically efficient instrument. He further lavished his time and skill in ornamenting every available part of the apparatus, whether the microscope were a tiny simple hand microscope, such as that made in Augsburg in 1686, or the elaborate compound microscope nearly two feet high, which furnishes the frontispiece of the catalogue. This microscope, which was made by Adams of Fleet Street about 1746, is of silver and most elaborately ornamented, so much so that, with its Corinthian column and allegorical figures, it looks more like a presentation centrepiece than a scientific instrument. There are several other interesting specimens by this maker which show the excellence of his work.

An earlier English maker was J. Marshall of Ludgate Street. In his microscopes the body or optical tube was generally covered with ornamented vellum or leather, and the mounts were of turned wood such as lignum vitæ. Lot 132, of which a full page illustration is given, is of twofold interest—firstly, because of the beautiful inlaid box base on which the compound microscope stands and in which it is to be packed, and secondly, because it was the property of Pope Benedict XIV, and bears the triple crown and the crossed keys in marquetry on its case. This Pope was elected in 1740, but whether he had any serious interest in science we know not. The perfect condition of the microscope and case and the completeness of the fittings suggest that they were not much or often used. Lot 255 is an extraordinary Dutch instrument, having a conical body two feet in length and a field lens five inches in diameter. This Brobdingnagian microscope is probably unique, but the same may be said of several other lots. Among the solar microscopes is one of which the body tube is supported by the uplifted arms of a carved allegorical figure, and another giant having a body twenty-four inches long and seven in diameter; only two instruments of the type are known; the other is in the Science Museum at South Kensington. There is a wealth of interesting objects in this collection.

Evolution of the Clinical Thermometer.—"Medicine is indebted to Galileo for the first contribution to thermometry," says William Shainline Middleton, in his article entitled Biographical History of Physical Diagnosis, which appeared in the December issue of *Annals of Medical History.* He goes on to say that "Galileo's first crude thermometer was constructed of a closed tube with a bulbous extremity. After heating this tube its opening was submerged in a vessel of water, whereupon the water rose to a certain level in the tube. Having established this point, the bulbous end of the tube was grasped in the hand and the body temperature was crudely measured by the expulsion of water from the tube, lowering the fluid level.

"Sanctorius (1561-1636), either ignorant of or disregarding Galileo's work, devised an instrument on improved lines for recording the body temperature by the mouth and to him belongs due credit for the first application of thermometry to medicine. The names of George Martine (1702-1741) and Carl Reinhold August Wunderlich (1815-1877) are inscribed indelibly in the development of clinical thermometry. The ubiquitous John Hunter (1728-1793) wrote his name in this field of clinical advance in 1766 by the following observation:

" 'I mentioned to Mr. Ramsden my objections to the common construction of that instrument (thermometer), and my idea of one more perfect in its nature, and better adapted to the experiments in which I was engaged. He accordingly made me some very small thermometers, six or seven inches long, not above two twelfths of an inch thick in the stem, having the external diameter of a ball very little longer than that of the stem, on which was marked the freezing point. The stem was embraced by a small ivory scale, so as to slide upon it easily, and retain any position. Upon the hollow surface of this scale were marked the degrees which were seen through the stem. By these means the size of the thermometer was much reduced, and it could be applied to soft bodies with much more ease and certainty, and in many cases in which the former ones could not be conveniently applied.' "

"The evolution of the clinical thermometer is a fascinating but intricate story. Suffice it to state that not until 1868, and through the offices of a contemporary clinician, Sir Clifford Allbutt, was the clinical thermometer developed in its present convenient form."

MAKERS OF MEDICINE

The beginnings of scientific medicine were made by the Greeks who may be truly termed the makers of medicine. Hippocrates knew and taught that diseases arose from the humors of the body and was indeed a scientific authority on dietetics, as he made clinical experiments to determine food values. He also wrote largely on medicine and surgery and on climatology. His knowledge of surgery was quite considerable. He applied the principle of extension in fractures as is done nowadays, and devised similar apparatus for the purpose. Hippocrates advocated trephining in contusions of the skull when the patient was unconscious but when there was no actual evidence of fracture.

Aristotle, perhaps the greatest of the Greeks, although not a physician had a deeper knowledge of physiology than any of the ancient sages. Galen, who by the way was a Greek by birth, and was educated in Alexandria, made valuable investigations of the nervous system and also investigated the anatomy and physiology of the brain and the spinal cord. For some centuries after the death of Galen not only was little progress made in the development of medicine but in many respects movement was retrograde.

It was in the fifteenth century that Vesalius in Paris first and afterwards in Padua began and continued those dissections which resulted in the publication of *The Structure of the Human Body* and was mainly instrumental in laying the foundation of anatomy. Harvey, profiting by the crude, but more or less true findings of earlier workers, Hippocrates, for instance, had observed that the bloodvessels were part of a connected system. Galen believed that the arteries contained blood not air; and that arteries and veins were connected, but he did not know that they were a closed system of branching tubes.

Servetus in the sixteenth century conceived the idea of a pulmonary circulation, and Andreas Cæsalpinus taught that blood flowed from the vena cava, through the right side of the heart to the lungs.

Harvey cleared up almost all the errors and laid the coping stone on the edifice imagined by others by describing the one action of the heart as the transmission of the blood and its distribution by the arteries to the extremities of the body, passing through the veins and thence to the right heart, lungs and left ventricle. However, Harvey had not been able to find the communication between arteries and veins. Four years after his death Malpighi observed the capillaries in the lung of a frog. Again for many years medicine remained comparatively dormant and it was not until the year 1830 and later when the microscope had been vastly improved that Schwann proved cells to be elemental parts of higher animals, a teaching confirmed and elaborated by Virchow in 1858.

The next epochmaking discovery was the germ theory of disease, which while led up to by many workers was completed by Pasteur in 1862 from which eventuated antisepsis and sepsis. Biochemistry promises to provide startling results and may inaugurate a new era in the conception of disease and the treatment thereof.

THE QUESTION OF EUGENICS

The question of eugenics is cropping up constantly. In some civilized countries the population is too large to be maintained or even fed adequately in existing circumstances. While in all civilized countries the least desirable part of the population is increasing out of all proportion and this is the case in this country. Restriction of immigration has been invoked to meet the situation. Civilization, as far as the number of inhabitants is concerned, is on the horns of a dilemma. There seems to be too great quantity and not enough quality. The intelligentsia, the cultured, the prosperous, and the fairly prosperous have few children, while the careless, improvident, and uneducated bear large families which, owing to environment and heredity, carry on the traditions of their parents. It is a problem bristling with difficulties and according to the eugenists can only be solved successfully by following their teachings.

There is little doubt that certain persons should not be allowed to propagate their species; those with mental defects, for instance, because they lack ordinary prudence and selfrestraint and reproduce their like without limit. It has been shown that a large proportion of criminals, habitual drunkards, and prostitutes, are likewise feebleminded and necessarily often influenced during the plastic years of youth by evil example and an environment of poverty and squalor. In the "good old days" such people were hanged or otherwise exterminated without mercy, and their offspring died like flies. Capital punishment has practically disappeared, and the children of the reckless and improvident are reared and educated, at the expense, more or less, of the thrifty and enterprising. It is no longer the survival of the fittest, but the survival of all who possess a spark of vitality, irrespective, to a large

extent, of their physical and mental equipment. It is obvious that the situation is precarious and even dangerous, and calls for remedies,—but are these remedies to be found in eugenics?

One of the latest propagandists of this mode of solving the problem is Dr. Barnes, the Bishop of Birmingham, who, arguing that the world at the present time is uncomfortably like "the world in that age of intellectual decline which heralded the break up of the Greco-Roman civilization, holds that the only way in which we can maintain our civilization depends upon whether we will listen to the eugenists and adopt measures to improve the racial quality of our people. But when we come to inquire of the eugenists themselves as to how this can be brought about, we find that there is no very definite eugenic plan. Professor Fleure, one of their leaders, speaking at the Educational Congress held recently in London, states there is not one best type of race, but many. Philosophers, American and European, have been deploring the decline of the great Nordic race, the big blonde people who have provided the majority of the governing classes in all the white nations. On the other hand, Nietzsche and other disrespectful men of science have alluded to this type as the "big blonde beast," and even Professor Fleure has had to allow that the simple mentality of this race is ill fitted to cope with the complications of social life and modern conditions. This seems to mean that people with brains are greatly if not chiefly needed. But how are these to be bred and surely the eugenists would not advise marrying or mating for the sake of brains alone.

Many eugenists in this country and in other countries insisted on the importance of having a clean bill of health before marriage, that is, the medical examination of those who desire to marry. There are, however, grave objections to this scheme. In the first place, who is to decide what physical or mental conditions or disabilities constitute a bar to marriage. Medical men themselves are not agreed as to which mental or physical defects or infirmities can be transmitted. It is agreed that feebleminded persons should not procreate, and the opinion is also almost unanimous that those infected with venereal disease, at least, in a gross form, or habitual drunkards should be debarred from marrying.

Again, is physical perfection the ideal to be reached in mating? A good physical equipment by no means signifies the possession of acute or able brains. Frequently, the contrary. It may be pointed out that infirm men and women of genius have not been rare, and that if eugenic laws had been in force, progress would have been much slower. The list of men and women of genius who have suffered from severe physical and mental disabilities and infirmities and who have given to the world gifts of incalculable value, is so long that it would easily fill an issue of this JOURNAL. Perhaps, it might not be an exaggeration to state that more men and women of genius have been weakly, sickly, and even crippled, than physically competent. Alexander the Great and Edgar Allan Poe were undersized, somewhat puny and neurotic men, strongly addicted to alcohol, and yet they played their parts and left names which giants of health must envy. In studying the problem of overpopulation and especially the overpopulation by those least fitted to carry the burden of life to the best advantage of all, eugenists seem to fail under existing conditions of knowledge regarding heredity. Broad principles of eugenics appear rationally clear, it is when the theory is submitted to searching analysis that no plain satisfying way out of the jungle is found.

ENCEPHALITIS LETHARGICA AND POLIOMYELITIS

While it seems to be the general view of the medical profession that encephalitis lethargica and poliomyelitis are specific diseases, there is much to say for the opinions of some medical observers that both these conditions are offshoots of influenza. In a communication to the *Lancet* December 30, 1924, Dr. F. G. Crookshank referring to the nervous element in lung collapse points out that atelectasis in poliomyelitis is a type of visceral paralysis which occurs with more or less frequency in this condition and in encephalitis lethargica and in influenza with nervous symptoms.

As a matter of fact the points of similarity in these conditions appear to suggest that these three maladies are not distinct but tend to run into one another, indeed, lead to the belief that encephalitis and poliomyelitis are offshoots of influenza. Dr. A. J. Brock, in a communication to the *British Medical Journal*, November 29, 1924, supplies arguments in support of Crookshank's thesis, that the occurrence of atelectasis, in influenza with nervous symptoms, in encephalitis and in poliomyelitis, is one more link in the proof of the incontestable and fundamental unity as Micheli calls it, between the cases at present sorted out under these various nosological labels.

In a further communication to the *Lancet* January 3, 1924, Brock expands the suggestion that there is a unity between these conditions by drawing attention to the fact that a more comprehensive mode of considering disease seems to be coming into vogue and in evidence of this change of attitude he refers to the note in the *Lancet* December 20th and 27th by Professor Ricardo Jorge on alastrim and variola and

to a letter by Dr. James Young, of Edinburgh, on bacterial pleomorphism in its issue for December 6, 1924. The note by Jorge is peculiarly suggestive, illuminating and instructive. It is true that the epidemics of smallpox which occur nowadays and which he designates alastrim are of a very much less virulent and deadly type than those which happened even a comparatively few years ago. The instance of the Province of Quebec in Canada is only one of the many cases in point. Nor is this due to vaccination, for vaccination protects from alastrim as effectively as from smallpox. In short, Jorge presents alastrim varicella, cowpox and the mild smallpox which are occurring frequently in different parts of the world as members of the varioloid family which differ but are related. Consequently Brock holds that under certain conditions of time and place, the different members of a group may run into one another, that one may in fact, i.e., clinically and for practical purposes, actually become another. These suggestions have much in their favor although they be opposed to the teaching of the day, and moreover have a considerable amount of clinical experience to uphold them.

Dr. Young illustrates from bacteriology the same principle enunciated by Dr. Crookshank and Professor Jorge from the clinical and epidemiological viewpoints. If encephalitis and poliomyelitis are offshoots of influenza and alastrim and some other complaints simulating mild smallpox are closely related to this disease and if as Dr. Young states various of the best known forms of microorganism, may, as a result of various changes in the medium develop from some kind of "bacterial plasm," our existing views as to the origin of disease may undergo somewhat radical revision.

HEALTH IN 1924

Whether or not a decreased death rate is, or is not, a sign of health, it seems to be the only indicator we have to use and it is at least a sign of decreased sickness. By this sign the year 1924 was, according to the experience of the Metropolitan Insurance Company, with its sixteen million industrial policy holders in the United States and Canada (about one seventh of the population of these two countries), the healthiest year ever known.

Among the causes which have contributed to the decline of the death rate over immediately preceding years, a mild winter was no doubt the most important. The combined death rate from influenza and pneumonia was 21.5 per cent. lower than for 1923, and the decline in the general death rate is accounted for chiefly by the abatement of these two related scourges. Influenze is, doubtless, on a periodical decline from lack of timber to work upon, but these two diseases are certainly made more frequent and more deadly by severe weather.

Typhoid reached a new low rate in the experience of the company. The report states that "the problem of typhoid control in America is now almost entirely one of rural sanitation." This disease is still looked upon with fatalistic unconcern in certain sections of the country, and the inhabitants are much more interested in the local "specialist" in the treatment of typhoid than in the health officer, who attempts to improve their water supply.

Tuberculosis reached a new minimum. Tuberculosis has, of course, been on the decline for a hundred years or so, and it has been been a mooted question as to how much of its falling off in recent years has been due to medical and public health work. There can be no question that these have influenced its decline to some extent, and as much by indirect as by direct methods. A safe milk supply probably is having more effect than any other condition. We are still much in the dark as to modes of infection, but doubtless most of it occurs through the alimentary tract and at an early age. Better living and better factory conditions have also contributed to the falling rate.

The rate for cancer is slightly less, but higher than for any year before 1921. The company estimates that "more than two per cent. of the cancer mortality during a period of twelve years has occurred among persons under twenty-five years of age." Also, "if a boy or a girl once reaches the age of ten, there is more likelihood of ultimately dying from cancer than from tuberculosis. . . . Of one hundred boys, ten years old, more than eight will eventually die from cancer, whereas less than seven will succumb to tuberculosis."

The death rate from diabetes declined about one point per 100,000 from that of 1923, doubtless due to the use of insulin.

The rate for chronic nephritis is the lowest in the history of the company; and for cerebral apoplexy, the lowest except for one year; while heart disease declined for the first time since 1919. "Under present conditions a child who lives to the age of ten is three times as likely to die of heart disease as from tuberculosis" and, of course, this likelihood increases with age.

The death rate from alcoholism declined slightly over that for 1923, though it is still much higher than for 1922, 1921, and 1920.

Though the general accident rate declined slightly, the deaths from automobiles increased to sixteen in 100,000. "Mortality from this cause has more than doubled since 1916, has tripled since 1915, quadrupled since 1913, and increased sevenfold since

1911. The automobile is responsible for four times as many deaths as railroads, and more than twice as many as by accidental falls or drowning."

ASTHMA AND ANAPHYLAXIS

Asthma in itself is not a fatal disease, and asthmatics reach not infrequently a green old age. In a book of addresses written by Dr. Arthur F. Hurst [*Essays and Addresses on Digestive and Nervous Diseases and on Addison's Anemia and Asthma.* London, William Heinemann, Ltd., 1924] it is pointed out that Sir JoJhn Floyer, who published the first book in the English language on asthma in 1698, was himself an asthmatic. In spite of this affliction, as Dr. Johnson put it he "panted on to ninety." Of late years a new light has been thrown on the causation of asthma. Several years ago Hurst defined asthma as the reaction of an overexcitable bronchial centre to blood borne irritants and to peripheral and psychical stimili.

The most recent investigations on the subject deal with the relation of asthma and anaphylaxis. Some of the incomprehensible individual variations in the etiology of asthma have been cleared up more or less. The irritant of the bronchi is generally a protein to which the sufferer is intensely sensitive. According to Hurst, whether a person who is sensitive to a certain protein will be unaffected by exposure to a moderate dose of it, or whether he or she will develop asthma, an urticarial or eczematous rash, an acute gastrointestinal attack depends upon whether he is otherwise normal, or whether he has an irritable bronchial centre, an irritable skin, an irritable digestive tract, or the irritable foci in the brain, upon which migraine and epilepsy respectively depend.

Walker, of Harvard, has made probably the most extensive researches into the matter. Walker found that fifty-two per cent. of four hundred cases of asthma and Coke in England found that the same percentage of three hundred and fifty cases, gave positive reactions to the cutaneous tests, which Walker was the first to use on a large scale for recognizing hypersensitiveness to proteins. Hurst's own experience and that of his colleagues and of other investigators in France and England with whom he has compared notes has been very disappointing, but he still thinks that the frequency of a toxic idiopathy as a factor in asthma has not been exaggerated by Walker or Coke.

The anaphylactic factor is most common in cases beginning in early life and the special liability in children is most marked with food proteins, and next with animal proteins. Sensitiveness to bacterial proteins and according to Coke, to feathers, is equally distributed whatever is the age of onset up to forty. With regard to pollen and hay fever investigations in this country have been much more extensive than perhaps in any country because the variety of pollens which cause the complaint is considerably larger than in Great Britain. As a matter of fact grass pollen is the only one of any great importance in Great Britain. As for animal emanations which may cause asthma in those unduly sensitive, Hyde Salter, in England, recognized this idiosyncrasy as long ago as 1859. Domestic animals as well as guineapigs, rabbits, hares, cattle, sheep and deer will bring on an attack, of which horse, cat and dog asthma are the most common by far. Hurst draws attention to the point that careful inquiry into the patient's history may lead to the discovery that attacks are caused by other animals, such as rats and mice, or even by parrots. Also asthmatics are occasionally sensitive to other proteins in addition to those referred to already. Indeed some of the idiosyncrasies to which asthmatics are prone are quite remarkable. Some asthmatics show a hypersensitiveness to aspirin.

There is a tendency among American writers in particular to range all the phenomena of the toxic idiopathies socalled under anaphylaxis, and according to certain French authors a toxic idiopathy or hypersensitiveness to a certain protein depends in part upon the fact that the protein has the effect of depressing the activity of the suprarenals. Hurst is of the opinion that usually only those functions in which the adrenal control is specially important for the particular individual are affected. Thus an asthmatic will have an attack of asthma, and a person with a sensitive vasomotor system will develop urticaria or other vasomotor disturbances of the skin. A man who has a tendency to gastrointestinal attacks owing to the abnormal irritability of his digestive tract will vomit and have diarrhea and abdominal cramp owing to exaggerated peristalsis and relaxation of the cardiac, pyloric and ileocecal sphincters. In this way is explained idiosyncrasies to shell fish, eggs and other foods, which are manifested by acute digestive disturbances. In some cases the idiopathy is exhibited in an attack of hay fever.

More or less frequently a general tendency to toxic idiopathies is inherited. This may manifest itself in different members of the family as asthma, hay fever or digestive disturbances, depending upon the inheritance or acquisition of an irritable bronchial, nasal, or digestive system respectively. While the investigations of research workers and of American workers, in particular, have demonstrated the cutaneous hypersensitiveness of many asthmatics to special foreign proteins, further research is needed before it can be accepted that anaphylaxis accounts for all cases of asthma, but it may be taken as proved that it is an important factor in many.

Obituary.

SIR THOMAS CLIFFORD ALLBUTT, K.C.B., P.C., F.R.C.P., F.R.S.

Cambridge, England

The sudden death of Sir Thomas Clifford Allbutt, regius professor of physics in the University of Cambridge, early in the morning of February 22d, at the ripe age of eighty-eight years, removed from British and international medicine a dominating figure, and from the University of Cambridge one of its most outstanding personalities.

Thomas Clifford Allbutt was the son of a clergyman in Suffolk, an agricultural county in the eastern part of England, and was born on July 20, 1836. He entered Cains College, Cambridge, where he gained several scholarships, taking his degree in arts with first class honors in the natural science tripos with distinction in chemistry and geology. He became Bachelor of Medicine in 1860, and began to practise in Leeds, where he was made physician to the General Infirmary. In 1882 he was elected a Fellow of the Royal College of Physicians. In 1892 he was appointed regius professor of physics in the University of Cambridge in succession to Sir George Paget, and physician to Addenbroke Hospital.

In 1881 he published a very important work on the ophthalmoscope in medicine. It may be said that his instrument was invented first by the late Charles Babbage, but attracted little or no attention until it was constructed in modified form by Helmholtz, and was brought back to its original form by Ruste. In the course of a few years it revolutionized knowledge of the internal diseases of the eye, and largely through Allbutt's comprehensive work it was demonstrated that the value of the instrument would not be confined to ophthalmic practice, but would be extended to the diagnosis of diseases of the brain and nervous system.

He invented a new clinical pocket thermometer, the former clinical thermometers in the late sixties were at once so cumbrous and fragile that outside the wards of a hospital they could be little used. The present clinical thermometer is due to his ingenuity.

In 1885, he published with Pridgin Teale, the well known Leeds surgeon who died at a great age a few years ago, a volume of clinical lectures *On the Treatment of Scrofulous Necks,* in which the authors advocated surgical intervention in place of the older *laissez aller* methods of allowing the tuberculous glands of the neck to come to a head and break, leaving unsightly scars. In 1884 he delivered the Goulstonian Lectures, on visceral neuroses, before the Royal College of Physicians; in the following year he lectured on scrofula and in 1896 on diseases of the heart. During the years 1896-99 he edited a great *System of Medicine,* with so striking and immediate success that a second edition was called for almost at once. In the preparation of this edition he had the aid of Sir Humphrey Rolleston. He was the author of many other publications, including *Science and Medieval Thought, The Historical Relations of Medicine and Surgery,* and *Diseases of the Arteries and Angina Pectoris.*

Allbutt was a remarkably active, energetic man, and in spite of his professional claims found tim for a great deal of public work. He was a membe of the Committee of the Royal Society and vice president from 1914 to 1916. He was also examine in medicine to the Royal College of Physicians i London, and to the University of Oxford. Honor were literally showered upon him by learne and scientific bodies. Among the honorary de grees which he accepted were the D.Sc. o Cambridge University, the D.Sc. of Oxford Uni versity, the LL.D. of Glasgow University, the M.D of Dublin University, the D.Sc. of Victoria Univer sity, the D.Sc. of Leeds University, the LL.D. o McGill and Toronto Universities, the Fellowship o the Royal College of Physicians of Ireland and of th New York Academy of Medicine, an honorary mem ber of the American Academy of Arts and Science and an honorary member of the Association o American Physicians. When approaching the ag of eighty, Allbutt in 1914 was elected president o the British Medical Association, and held that posi tion during the trying years of the war.

Allbutt took an active part in the wordy and pe and ink warfare aroused by the passing of the Na tional Health Insurance Act in 1912. He took th stand that the act must create and nourish a spiri of research and of scientific diagnosis and provid for these pursuits accordingly. He argued that th scheme must not encourage the nation to rely o curative and remedial medicine alone, but must creat a preventive medicine by promoting researches int the causes of disease and the means of prevention.

He lost no opportunity of impressing his views o the profession and the public that prevention of dis ease was of greater importance by far than treat ment, and that efforts to stamp out or abate disease should be centred largely in providing means fo finding out the causes of disease and for preventing them from developing. It is somewhat of a coin cidence that two great British physicians who held these opinions, Sir James Mackenzie and Sir Clifford Allbutt, should have passed away within a few weeks of each other. Both, too, it may be added, concentrated much of their attention on diseases of the heart and circulation. Allbutt had decided views concerning diseases of the arteries and angina pectoris. He was a man of commonsense and had little patience with medical fads and obsessions.

Personally, Allbutt was one of the most charming of characters. Unlike most great men he was loved even more than he was respected. His learning was both extensive and varied, in fact, an old friend o his at Cambridge, himself a Fellow of Cains College, once said to the writer that Allbutt was so versatile that he sometimes wondered how he had found time to acquire his deep knowledge of medicine. He possessed unfailing courtesy and a remarkable sweetness of temper, combined with wit, wisdom, and humor.

An appreciation of this great physician and fine gentleman in the highest sense of the words, will be incomplete without mentioning his unusual gift of diction and phraseology. He was a good speaker, but a writer of an almost unique distinction. Among the medical writers of his generation he towered. By the death of Sir Clifford Allbutt, the medical profession of English speaking lands has lost its chief link between Victorian and modern medicine.

News Items.

Doctor Ney Honored.—Dr. K. Winfield Ney, dean of the New York Polyclinic Medical School and Hospital, was guest of honor at a dinner given by the teaching staff at the Hotel Astor, March 7th.

Presbyterian Hospital Fund.—The campaign for the Columbia-Presbyterian Hospital Medical Centre is still being carried on. The most recent report announces a total of $2,294,990. Gifts recently reported are $500,000 from Mrs. Stephen V. Harkness, the largest single donation, and $400,000 from an anonymous donor.

Recognition for Doctor Dick.—The following cable sent to the Nobel Prize Committee of Stockholm by the board of directors of the New York Committee of the Gorgas Memorial, has been made public: "Gorgas Memorial Institute of Tropical and Preventive Medicine respectfully recommends for consideration by the Nobel Prize Committee, Doctors George and Gladys Dick of Chicago, in recognition of their work in prevention and cure of scarlet fever."

Admittance of Students to Johns Hopkins.—Changes have been made in the method of admitting medical students to Johns Hopkins, limiting admittances to "Grade A" candidates after individual study of the applicants. It is expected this will reduce the classes to fifty-five or sixty, although seventy-five will be accepted if qualified. Personal interviews with the assistant dean, or with regional representatives in case the student lives at some distant point, will be required.

Leonard Prize for Research.—The American Röntgen Ray Society will award one thousand dollars to the author of the best piece of original research in the field of röntgen ray, radium, or radioactivity (not involving a patent or copyright). Papers must be in English, and submitted not later than May 1, 1925, and the winning article must also be presented at the annual meeting of the society, September, 1925. The prize commemorates Dr. Charles Lester Leonard, a martyr to his research in the field of the röntgen ray. Details of the competition may be obtained from Dr. George W. Grier, Chairman, 8088 Jenkins Arcade, Pittsburgh, Pennsylvania.

Dedication of Sterling Hall at Yale.—The Sterling Hall of Medicine, a $1,425,000 building made possible by the bequest of John W. Sterling of the class of 1864, was recently dedicated at Yale University. Mr. Sterling, a noted corporation lawyer, who died in 1918, left the bulk of his estate to Yale, from which the Sterling Chemistry Laboratory was built, and which will provide the Sterling Memorial Library. The new Hall of Medicine is opposite the New Haven Hospital. It provides an auditorium seating two hundred and fifty. The building was presented to the university by George Hervey Church, representing the trustees of the estate, and was accepted on behalf of the university by Dr. James Rowland Angell.

Gorgas Memorial Meeting.—The executive committee of the Gorgas Memorial recently held its first meeting at the New York Academy of Medicine. Additional members elected to the executive committee were Dr. Nathan Van Etten, Dr. Wendell Phillips, Mrs. William G. Willcox, and Mr. George Gordon Battle. Dr. Ernest Fahnestock was appointed chairman of a citizens' committee for New York City, and Dr. Samuel Kopetsky was elected chairman of an advisory publicity committee. A series of radio talks were proposed, the first to be an address of Dr. George David Stewart, to be given before physicians and laity at the Fifth Avenue Hospital, Gorgas Memorial Evening, Wednesday, March 18th. Generous response was reported to the appeal for a five million dollar endowment.

Personal.—Dr. William Seaman Bainbridge of New York delivered an address on The Present Status of the Cancer Problem before the American Röntgen Ray Society, meeting at Detroit, February 19th.

Dr. Mabel E. Elliott, well known for her relief work in the Near East, will go to Japan in the near future as a medical missionary under the National Episcopal Missionary Board.

Dr. Arthur A. Landsman gave a paper, by invitation, before the Bronx Physicians Club, on Causes of Bleeding from the Rectum, on February 19th.

Dr. H. Harris Perlman, instructor in diseases of children at Jefferson Medical College, Philadelphia, has been appointed medical director of the Ocean City Seashore Home for Babies, Ocean City, New Jersey.

International Congress on the History of Medicine.—The fifth international congress on the history of medicine will be held from July 20th to 25th, at Geneva, Switzerland.

International Birth Control Conference.—The sixth International Neo-Malthusian and Birth Control Conference will be held at the Hotel McAlpin, New York, March 25th to 31st.

Meeting of American Stomatological Association.—The New York state society of the American Stomatological Association will hold its last monthly meeting Tuesday, April 14th, at the New York Academy of Medicine, to which all practitioners are invited.

Course in Medical Diagnosis.—Conferences in medical diagnosis and pathology will be given by Columbia University, at the Presbyterian Hospital, to graduates in medicine, from June 1st to July 10th. Dr. George M. Mackenzie and Dr. William C. Von Glahn will be instructors.

Lectures at Johns Hopkins.—The Charles E. Dohme Memorial lectures for 1925 will be given at Johns Hopkins University Medical School, May 8th to 11th, by Dr. Arthur R. Cushny, professor of pharmacology of the University of Edinburgh, on the subject of Optical Isomers in Biology.

Tuberculosis Institute.—A regional institute for tuberculosis workers will be held in Philadelphia March 25th to April 8th, by the National Tuberculosis Association and the Pennsylvania School of Social and Health Work, for the purpose of studying methods of education and organization.

International Congress on Military Medicine and Pharmacy.—The third international Congress of Military Medicine and Pharmacy will be held in Paris, April 20th to 25th, at Vâl-de-Grace. All officers belonging, or having belonged to the army or navy medical corps of allied, associate, or neutral nations, are invited. There will be scientific meetings and demonstrations of equipment.

Lectures on Medical Hydrology.—The University of London announces a course of lectures on medical hydrology to be delivered at the University (South Kensington) with demonstrations and lectures at Buxton, a British spa, to be given from April 27 to May 2. Applications with fee of £1 1s. should be received before April 17th, by Miss Hilda Fox, University Extension Department, University of London, South Kensington, S. W. 7, London.

Course in Public Health Work.—The University of Michigan announces a six weeks' summer session in public health, from June 22nd to July 31st. The courses will be conducted by members of the faculty, augmented by special instructors of national reputation. A bulletin of information may be obtained from Dr. John Sundwall, Director, Division of Hygiene and Public Health, University of Michigan, Ann Arbor, Michigan.

Northwestern University News.—The new dean of the medical school is Dr. Irving Samuel Cutter, for ten years dean of the college of medicine of the University of Nebraska. The former dean, Dr. Arthur I. Kendall, has accepted an appointment as professor of bacteriology and public health at Washington University Medical School.

A Chicago physician, who requests that his name be withheld, has given the sum of $150,000 to the medical school, for instruction in clinical medicine, and for assistance to the poor and unfortunate of the city.

Society News.—The New York Ophthalmological Society has elected the following officers: President, Dr. Henry H. Tyson; vice-president, Dr. W. G. Reynolds; secretary and treasurer, Dr. John H. Dunnington.

A joint meeting of the Philadelphia Academy of Surgery and of the New York Surgical Society was held at the New York Academy of Medicine, February 25th.

The following officers for 1925 were elected by the Kings County Homeopathic Society, at its annual meeting held January 27th at the Cumberland Hospital: Dr. Charles A. Brown, president; Dr. Royal A. Abbott, first vice-president; Dr. H. S. Ducret, second vice-president; Dr. Farrand Pierson, secretary, and Dr. C. J. Ohlbaum, treasurer. Because of the clinical facilities offered it is proposed to hold all its future meetings at hospitals.

The Medical Association of the Greater City of New York, at its recent annual meeting, elected the following officers for 1925: President, Dr. Louis Faugères Bishop; vice-president, Dr. Thomas C. Chalmers; recording secretary, Dr. Ernest Ellsworth Smith; chairman for the borough of Brooklyn, Dr. Robert E. Coughlin; chairman for the borough of Richmond, Dr. William Bryan; chairman for the borough of Queens, Dr. Henry C. Courten.

Book Reviews

TREATMENT

Physiological Principles in Treatment. By W. Langdon Brown, M.A., M.D., Cantab., F.R.C.P. Fifth Edition. New York: William Wood & Company, 1924. Pp. 511.

This splendid book, and now its fifth edition, lives right up to its title. The author makes every sentence say something definite, and therefore the book furnishes ready, quick information on physiological facts so necessary for rational therapy.

The author has covered a great deal of ground in this small book, which includes a very complete index. He gives briefly some of the facts on organotherapy; a very complete discussion of the digestion; disturbances of the stomach and intestines; advice on rectal feeding, and he well discusses the functions and ordinary diseases of the pancreas and liver. He has an up to date chapter on diabetes, acidemia and ketosis; carefully discusses proteins and their metabolism and the various normal and abnormal excretions of the kidneys. The chapters on vasomotor disturbances, hypertension and irregularities of the heart are all brought, in this edition, right up to the present time. The last chapters of the book are devoted to the subject of vitamines and calcium metabolism.

If every practitioner would keep up with the science of physiology, nutrition and chemical biology he would be more rational in his treatment of disease and abnormal conditions. This book aims to help the practitioner toward that end, namely, to have his therapy based on the foundation of the physiological and biological processes of the body.

BIOCHEMISTRY

Principles of Biochemistry. For Students of Medicine, Agriculture, and Related Sciences. By T. Brailsford Robertson, Ph.D., D.Sc. Second Edition. Thoroughly Revised. Illustrated with Fifty-seven Engravings. Philadelphia and New York: Lea and Febiger, 1924. Pp. 796.

The second edition of this classical work contains much additional matter as compared with the first. The new sections that will probably appeal most to physicians are those dealing with the neutrality of the blood, metabolism in diabetes, growth, and the relationship of growth to diet.

The volume as a whole remains a model of what a textbook may be when knowledge of the subject, common sense, imagination, skill in exposition and native charm of style combine in its production.

Contrasting this book with the standard physiological chemistries of one or two decades ago, one is struck by the ever widening associations of the subject, not only with every field of modern medicine, but also with the parent subjects of physiology and biology and the related sciences of agriculture and industrial chemistry. Besides, at every turn, increasing use is made of mathematical concepts and of the laws of physics and physical chemistry. These are indeed the very things that so often appear to "practical" physicians, as insuperable barriers to the acquisition of what is after all a new science. Yet, such is the didactic skill of the author, so obviously sincere his willingness to "explain from the bottom" whenever he senses a possible difficulty in the mind of his reader, that even the most hurried practitione can hardly fail to find pleasure as well as prof in the pages of this volume.

It is always a difficult task to select for specia comment individual sections in the face of so excel lent a presentation of so broad a subject. In additio to the basic chapter on the food stuffs themselves there are most stimulating discussions on the genera properties of protoplasm (containing chapters o crystalloids and colloids), on the chemical correla tion of tissues (with chapters on the blood and lymp and on the chemical regulation of circulation, diges tion, generation, and metabolism); on the chemi cal processes which underlie life phenomena (includ ing here the chapter on growth): on the products o tissue activity; and lastly on the energy balance o the organism.

The final chapter on the outlook—which for tunately has been reproduced in toto from the firs edition—remains a splendid essay on what biochem istry may be expected to give to our industrial life to agriculture, to food conservation and food syn thesis, and to medicine—particularly to therapeutics immunology, and to the control of senesence.

VENEREAL INFECTIONS IN WOMEN

Common Infections of the Female Urethra and Cervix. B Frank Kidd, M.A., M.Ch. (Cantab.), F.R.C.S. (England and A. Malcolm Simpson, B.A., M.B., D.P.H. (Cantab.) With Additional Chapters by George T. Western, M.D and M. S. Mayou, F.R.C.S. Oxford Medical Publications London: Humphrey Milford; New York: Oxford Uni versity Press, 1924. Pp. xii-191.

The authors have assumed the task of elevatin venereal diseases to that same dignified level ac corded to other specialties. This book is the resul of intensive efforts in that direction.

A chapter is devoted to general diagnosis an shows how to examine a woman suspected of gonor rheal taint, so as to determine the presence or ab sence of infection, or the fact of cure. The succes sive steps in this procedure are cited. The femal venereal clinic should be a sorting house for wome who are admitted to the hospital for a vaginal dis charge or painful micturition. The author insist that the venerologist should not confine himself t this specialty and that he should have training i gynecology and genitourinary surgery as well as i general surgery and medicine. The chapter on gen eral treatment is well worth reading and gives th most minute care to the details of management. Th special diagnosis and treatment of vulvitis, vaginiti and bartholinitis includes also notes on pudenda sores and their management. The diagnosis an treatment of urethritis and its complications is valu able as it contains much useful information. Th same may be said of the chapter on the diagnosis and treatment of cervicitis. The treatment, particu larly, is discussed in great detail. The chapter or endometritis, salpingitis, oophoritis, pelvic cellulitis and peritonitis, which, strictly speaking, are some what extraneous to the subject of the book, may wel be included because of their complicating nature Gonorrhea in female children, that bugbear of in-

stitutions for female children, is given the attention that it deserves. The treatment of gonococcal arthritis in women is presented in painstaking detail.

The bacteriology of the gonococcus is discussed by G. T. Western and ophthalmia neonatorum is taken up by M. S. Mayou. There is also a chapter on gonococcal proctitis, osteitis and the use of vaccines. It is maintained that the principle of artificial immunization by means of vaccines holds out the most hopeful line of research for the discovery of a specific and rapid remedy for gonorrhea. There is still much work, however, to be done along these lines.

In the chapter on prophylaxis, the keynote of the whole situation is said to lie in properly designed and properly used prophylactic packets. They should not be given out promiscuously. Delayed prophylaxis allows its use the next morning, when it is more likely to be used intelligently and deliberately.

An appendix contains an analysis of 650 consecutive cases examined at the Female Gonorrhea Section of the Venereal Clinic of the London Hospital, 1917 to 1920.

This book may well be recommended to those interested and is a valuable contribution to the literature. Its style is impressive and it is full of valuable information on the subject.

LIFE INSURANCE

Life Insurance Examination. Edited by Frank W. Foxworthy, Ph.B., M.D. St. Louis: C. V. Mosby Co., 1924.

Including the editor, this book represents the collaboration of fifty associates who are experts in the subjects of which their chapters treat. The chapter on the history of life insurance is extremely interesting, and the forty-seven subsequent chapters treat of every branch and subject of human life, health and disease that can be of interest and instructive to a medical examiner of insurance risks. Many of these chapters also show the problems and the operation of the medical departments of insurance companies.

Many parts of this book, with illustrations, would seem out of place in a book on life insurance examinations. They really partake of the practice of medicine, and laboratory examinations that are rarely made by the medical examiner. Such parts might have been omitted but of course they make the book more complete for reference. The whole object of the book is to raise the standard of the medical examiner.

On page seventy-eight it is stated that the medical examiner is the "eyes of the medical department," and the success of the insurance company depends upon his honesty and his professional and personal attainments.

On page 113 it is stated that the medical examiner is appointed solely on his professional attainments and qualifications. This is generally the case, and should always be the case, but as a matter of fact, very frequently medical examiners are appointed at the instance and urge of the agents in the field.

In the chapter devoted to the examination of women, the examiner is told to have the woman disrobe the upper part of her body, and then with safety pins to fasten a front and back towel draped over her, and then the examination may be made at the loopholes at the side by lifting the towel. This advice is absolute perfect nonsense. In this age of women who wear little most of the time and almost nothing at dances and at the seashore, to hamper the examiner with the rubbing and rasping of towels on the stethoscope is absurd. The risk of accepting a female applicant is greater than the risk of accepting a male applicant. On what ground should the medical examiner be hampered? Also, the abdominal examination of female applicants is not sufficiently emphasized, which is very evidently quite important.

With all these many chapters aiming towards the efficiency of the medical examiner, there is not a single word on the compensation that the medical examiner should receive. He is required to be at the top notch of the medical profession, and with the enormous number of questions now asked, with the extra scientific physical examinations that he must make and then plot some of his findings on diagrams, his fee, for practically an hour of professional scientific work, is only five dollars. This same amount was the fee paid about fifty years ago. Every other employee of an insurance company from the woman cleaner and the office runner to the president has had her or his wages or salary trebled and quadrupled. What about the examiner in the field who is "the eyes of the company"? When will the worm turn?

The reviewer believes that this is probably the best book that has been written on the subject of life insurance, and it should be owned by every examiner.

NUTRITION

Nutritional Physiology. By Percy Goldthwait Stiles. Fifth Edition. Philadelphia and London: W. B. Saunders Company, 1924. Pp. 307.

This (fifth) edition of Stiles's helpful book includes the new work on insulin and on the vitamines.

The book remains a needed and useful introduction to that bugbear of the student and older practitioner—the subject of nutrition. The presentation is lucid and the style informal and pleasing. The method of simplifying the explanation of difficult concepts by the use of homely similes is much to be recommended.

The book should be a great aid to students and to physicians wishing to follow the "newer metabolism."

Fasting and Undernutrition. A Biological and Sociological Study of Inanition. By Sergius Morgulis. New York: E. P. Dutton and Company, 1923. Pp. 407.

In Professor Carlson's book, *The Control of Hunger in Health and Disease,* written in 1916, occurs this passage: "The layman may question the practical utility of hunger control to society on a whole, in view of the fact that it has played no rôle in past evolution. . . . *In these times of plenty* (italics ours), overfeeding . . . is on the whole more prevalent than malnutrition."

Less than a decade later appears the work of Professor Morgulis on *Fasting and Undernutrition.* During the interim society has been rent by conflict, plenty has largely been succeeded by want, and want by starvation. What was in 1916 the special and leisurely study of a few learned experimenters has now become the anxious concern of untold thousands—and the scientific reading public is therefore in a particularly receptive mood to welcome Morgu-

li's book as a second great American contribution to the subject of hunger and malnutrition.

Morgulis begins his work with a splendidly written —the style throughout is excellent—introductory chapter and then proceeds to divide his subject into three parts: Physiological Inanition; Experimental Inanition; and Inanition and Growth. In each of the first two groups he discusses in turn the associated chemical, physiologic and morphologic phenomena.

Under the heading of physiological inanition the author discusses hibernation, metamorphosis and the inanition of the breeding season in salmon. Experimental inanition covers the subjects of more direct clinical hearing such as acute inanition, partial inanition (including vitamine starvation), chronic inanition and intermittent inanition. The book closes with an exhaustive international bibliography (almost one hundred pages) and an author and a subject index.

Morgulis's book is not a clinical treatise, yet it should be in the hands of every physician, not only as a reference guide to all the known facts pertaining to the subject, but as an inspiration and a powerful stimulus to think of malnutrition, to diagnose malnutrition, and to prevent and treat this ever present, but heretofore sadly neglected condition.

LAURENCE STALLINGS

Plumes. A novel by Laurence Stallings. New York: Harcourt, Brace & Co., 1924.

What Price Glory. A play by Laurence Stallings and Maxwell Anderson. Unpublished.

"What chance has that poor little boy . . . against all these dead men?"

Thus Richard Plume's struggle to find himself ends. He, too, was just a poor little boy inspired by the traditions of the past. He meets actuality, ghastly facts that elders have lied about, silvered over with romance, with the colored tatters of forgetfulness. They also had had to continue the lie or see their souls perish. The old men ruling the mob; the individual who dares to oppose the old men, mobbed. Emotional responses of archaic times persisting to this day everywhere! And man's manual skill, his artisan intelligence inventing, plotting devices good and evil, building "civilization" only to tear it down again as soon as the primitive emotions are touched. We have no right to call ourselves civilized as long as there are wars. No ancestor worshippers are civilized—in the ideal sense of the word. To be able to live as a herd—that is all our socalled civilization really means. And anyone threatening that herd is thrown out, pilloried, crucified in true pagan fashion.

Plumes should be read and reread by everyone till some hint of its everlasting truth penetrates the thickest mob brain. *What Price Glory* should be seen till the protesters begin to recognize the pathological nature of their herd reaction. Lawrence Stallings's works should be rammed down the throats of those who sit back complacently and try to escape by murmuring "Very interesting." They should be used as a flail for those whose shivering flesh cannot bear the "unnecessary." When that vast body of the middle class understands its own orgastic pleasure in the sacrifice to the past on the altars of war, understands and feels in new terms of emotion, then there may be hope of civilization!

The book of *Plumes* gives the postwar attempt at readjustment of one Richard Plume. His ancestors have broken themselves for tradition and war glory. Like a disease handed from father to son it riddles them all. Richard Plume as he struggles to come up from the abyss where all his ties to life and human thought lie shattered, determines he shall be the last to be so sacrificed. But the "old men," mob worship, mob emotion, stand just as unmoved, casting their jagged shadow over his happy little son.

This is the story of a soul fighting against the world. This is the story of a man seeking to know himself. The rest of the world crashes inevitably as he rears his head through the temple top. Like Samson he is caught in its downfall. But Samson was killed in those far away days. Plume is only pinned down; he may free himself yet.

This then is the core of Stallings's mental life. The sparks that are shot out by the hammering on that essential core turn to individual jewels. *What Price Glory* dwells for a moment on the tinsel garments of war. People don't like to see anything naked, and these garments turn out to be so paltry, so filthy, that by contrast the pure hard tragedy of war can be realized. For once someone has got past the trappings. Lawrence Stallings and his coworker, Maxwell Anderson, are turning the very words of the mob inward. Perhaps after all these centuries the primitive mouthings will sound for what they are worth. I do not mean the language of *What Price Glory.* I mean the "Back to Democracy," the "shocking," the "unnecessary," all the ready phases of those who borrow their minds from their ancestors, not to use by any chance, but just to have handy in case there is any "thinking" to be done.

Medicoliterary Notes.

Dr. Robert Oleson, of the U. S. Public Health Service, has recently completed a thyroid survey of elementary school children in Cincinnati, the results of which have been published as Reprint No. 941 from the *Public Health Reports.*

* * *

The *Forum* for March contains a number of articles of unusual interest. Among them are Is Paychoanalysis a Science? in the form of a debate between George Sylvester Viereck arguing for the affirmative and Aldous Huxley for the negative; America and Roman Catholicism by Michael William; What Is Civilization?—The Answer of the Middle Ages, by Ralph Adams Cram; Biology Moulding the Future, by J. B. S. Haldane; and The Christianity of Christ, by Joseph St. Loe Strachey.

* * *

Dr. Louis I. Dublin, of New York, contributes an interesting article to the December number of the *Nation's Health* on the automobile as the outstanding cause of highway accidents. Accidents due to all other vehicles, including steam and electric railways, horse drawn vehicles, bicycles and motor cycles, have decreased steadily; fatal automobile accidents have just as steadily increased.

* * *

Legislation regarding the preservation and promotion of the public health must and will be considered and passed for many years to come. There is no reason why it should not be scientific, practical, adequate, and successful if the sponsors of such legislation when drafting it will follow common sense rules. . . . Then will a law survive the test of the courts and be a reasonable, admirable, and ideal

method of safeguarding the nation's most valuable asset, the health of its people.—J. A. Tobey in *How to Draft New Health Legislation.*

* * *

The most interesting plays now running, judged from a psychological point of view, are *What Price Glory?, They Knew What They Wanted,* and *Candida;* in a second class, of interest but not so perfectly done, may be mentioned Joseph Schildkraut in *The Firebrand,* supposedly a chapter from the life of Benevenuto Cellini; Mary Blair in Eugene O'Neill's *Different;* George Arliss in Galsworthy's *Old English;* and the much discussed *Desire Under the Elms.*

* * *

The literary reviews of England, where Jeanne Bordeux's *Life of Eleonora Duse* has been published by Hutchinson & Company, seem for the most part to find the book a sincere outpouring of love and admiration on the part of the author, and an accurate presentation of the facts of the great actress' life and career, but "florid rhetoric and gushing torrents of unmeasured praise," and "overloaded with emotional commentary."

* * *

As an aid in giving the findings publicity, and that they may be available to a wider public, the *Nation's Health* for December reprints the major conclusions of the final summary report of the Framingham Community Health and Tuberculosis Demonstration. The report of this demonstration (Framingham Monograph No. 10) is an outstanding document of the present day movement in health fields, and is deserving of the most careful study and consideration by all workers in the field.

* * *

The Alienist in Court is the title of an article in the February *Harper's* by Dr. Joseph Collins. It is a discussion of expert testimony.

* * *

The total number of typhoid carriers listed in New York State, exclusive of New York City and State Hospitals, on October 1, 1924, was ninety-six, according to *Health News.* Of this number twelve were discovered and added to the list after January 1st. These twelve carriers are considered to have been responsible for fifty-three known cases of typhoid fever. Eight of these carriers were discovered as the result of efforts of local health officers, two by attending physicians, and two by representatives of the state health department.

* * *

The much discussed portrait of Lady Astor, which was removed not long ago from Guildhall in the House of Commons, is still, the British press reports, under consideration, but in the meantime the picture is being loaned to the Bedford College for Women. This is the oldest university college for women in England. It had among its early students George Eliot and the daughters of Dickens and Cobden.

* * *

The Rockefeller Foundation has made a grant to the Canadian National Committee for Mental Hygiene of $75,000 for research, experimentation and mental hygiene as applied to school children. The grant was made with the understanding that an equal amount be subscribed from Canadian sources.

* * *

Recent medical publications of interest are *Building Strong Bodies* by Dr. Woods Hutchinson; *The Degenerative Diseases,* by Dr. Lewellys F. Barker and Dr. Thomas P. Sprunt; *Diabetic Diet,* by Doris McHenry and Marjorie M. Cooper; *The Psychology of the Preschool Child,* by Baldwin and Stetcher; and *The Psychology of Emotion,* by Dr. John T. MacCurdy.

* * *

Movies that should not be missed are *Peter Pan,* with Betty Compson in the title part and Mary Brian as an equally able Wendy; *The Last Laugh,* a German production; *The Miracle of the Wolves,* with beautiful winter scenes photographed in the French Alps; *The Lost World,* particularly interesting as the best example yet shown of double film work and the use of small models to represent the monster creatures of the primeval world. A picture of special interest will be released in New York City in the near future, according to announcement. This has been in preparation for several months in Samoa under the direction of Mr. Robert J. Flaherty, producer of *Nanook of the North.* The actors in the picture are all Polynesians, members of what is considered the finest primitive race in the world, and the story is woven about the coming to manhood of the young hero. All the festivities and ceremonials, including the tattooing, are reproduced in detail. The production should be a significant contribution to folklore and manners and customs of primitive peoples.

* * *

A recent statistical report on accidents and their causes and time incidence, states that the peak hour for children's street accidents is five o'clock in the afternoon, comparatively few occurring in the forenoon when both children and drivers are less tired and more alert.

* * *

The Dickens Fellowship is making an appeal for £10,000 to endow the house in Doughty Street where Dickens lived for several years. This house has been until recently a boarding house, but has been bought by the Fellowship and will be opened in the coming summer as a Dickens Museum, containing many relics, books and pictures.

* * *

Both Berlin and Dresden have public consultation centres on marriage relations. The Berlin centre is located in the recently founded Institute for Sexual Science, conducted by Magnus Hirschfeld. Persons contemplating marriage are advised as to health and general personal fitness as to being a mate and parent; sexual and psychic difficulties and questions of child training may also be brought to these centres for advice and discussion.

* * *

Mary Austin, the well known writer on the American Indian, has in *McNaught's Monthly* for March an article entitled Creative Genius and Sexual Freedom which is interestingly written and gives considerable food for thought.

* * *

Pio Baroja, whom many consider the foremost living novelist of Spain, practised for a short time as a village doctor. He tells us in his autobiographical notes, called *Youth and Egolatry,* that he failed three consecutive times in his medical examinations, and, in fact, never succeeded in getting a passing grade until he learned the subjects by rote. He persevered, however, until he received his degree from the University of Madrid. "One day I read—or it may have been one of the family," he casually writes, "that the post of official physician was vacant in the town of Cestona. I decided to apply for the place and dispatched a letter accompanied by a copy of my diploma. It turned out that I was the only applicant, and so the place was awarded to me. . . . I realized in Cestona my childish ambition of having a house of my own, and a dog, which had lain in my mind ever since reading *Robinson Crusoe* and *The Mysterious Island.* I also had an old horse named Juanillo, which I borrowed from a coachman; but I never liked horses. . . . I committed no blunders while I was a village doctor. I had already grown prudent, and my sceptical temperament was a bar to any great mistakes." We can readily see that medicine was not the profession for Baroja. He soon realized this himself and went into the baking business. *Youth and Egolatry* is a very readable, entertaining book.

* * *

The New York State Committee on Mental Hygiene of the State Charities Aid Association has recently issued a leaflet on *First Aid for the Mentally Sick.* It is a plea that patients awaiting admission to hospitals for mental diseases be given the proper care.

* * *

In the June, 1924, issue of *Revue De La Tuberculose,* Paris, the following interesting articles appeared: *La hernie du médiastin au cours du pneumothorax thérapeutique,* by Dr. Dumarest and Dr. Brette; *Valeurs respectives des données manométriques et de la radiologie dans le pneumothorax artificiel,* by Dr. E. Leuret and Dr. P. Delmas-Marsalet; *Présence du bacille de Koch dans le liquide duodénal retiré par tubage,* by Dr. D. Olmer and Dr. Albert Crémieux; *Revue critique des techniques expérimentales, et cliniques applicables à la tuberculose,* by Dr. André Bergeron and Dr. Raymond Letulle. This issue also contains an unusually large review of publications on bacteriology, tuberculin, etiology, pathology and laboratory experiments.

Abstracts from Current Literature

GYNECOLOGY

Erythrocyte Sedimentation Test in Gynecological Diagnosis.—Frida Becher-Rüdenhof (*Wiener klinische Wochenschrift,* May 29, 1924) uses the sedimentation test in every case and is guided by the following conclusions:

1. The sedimentation test is a valuable aid in determining whether the adnexal tumor is of an inflammatory nature, and therefore in the differentiation of neoplastic tumors and tubal pregnancy and other inflammatory salpingitides. It also indicates the presence of a suppurative or inflammatory process in cases where neither the leucocytosis nor the rise of temperature is indicative.

2. This test enables us to determine the presence of complications in the postoperative stage of a disease, such as suppuration, pyelitides and metastases at a time when no other symptoms or signs give such information.

3. The test may be done quickly and easily, particularly because it is not necessary, for practical purposes, to wait for complete sedimentation, as even after a few minutes it shows whether the sedimentation is of type I, II, or III.

The disadvantages of the test are, particularly, that it takes a very long time before the normal sedimentation is restored after a suppurative or inflammatory process. Furthermore, the practical utility of the test is minimized by its excessive sensitiveness, whch gives information about various insignificant processes. By the utilization of only great differences in the test this disadvantage may be eliminated. Nevertheless this test is of diagnostic significance in only a very limited number of disease pictures.

Operation for Retroflexion of the Uterus and for Prolapse.—Felix Franke (*Zentralblatt für Gynäkologie,* June 28, 1924) reports some very good results with the retrouterine suture of the round ligaments drawn through the broad ligaments posteriorly (which are then sutured to the posterior surface of the uterus, so that the uterus rides upon them as on springs). His results are excellent since he sutures the ligaments with silk and makes the patient wear a pessary for twelve days after the operation. A thorough emptying of the intestinal canal should precede the perineal plastic and the stools should then be restricted by keeping the patient on a restricted diet for ten to twelve days.

In cases of prolapse in women of the childbearing age he forms a narrow strip from the fascia of the rectus muscle on both sides, divides the lower base, punctures the rectus muscle and peritoneum on both sides with a forceps and brings the round ligament through this rent and carries the fascial strips under the ligaments through the reduplications of the peritoneum so that they ride upon the strips.

Complete Hysterectomy.—G. C. Reid (*International Journal of Medicine and Surgery,* September, 1924) presents the operative technic in full, and strongly advocates complete hysterectomy in preference to supravaginal ones, for both malignant and nonmalignant disease. In cases of nonmalignant disease postoperative symptoms which occur frequently in supravaginal hyesterectomies, such as leucorrhea, pressure pains, pruritus, etc., do not occur. Many of the infected uteri, if only taken out supravaginally, leave a small focus of infected cervical tissue which keeps up a local irritation or may be the cause of a focal infection and the beginning point for a cervical carcinoma. A small piece of cervical tissue will often cause severe hemorrhages even years after the primary operation.

Excision of Cervix for Endocervicitis.—S. Rottenburg and G. Schwartz (*Surgery, Gynecology and Obstetrics,* November, 1924) state that chronic endocervicitis is an infectious process involving the glands in the cervical mucous membrane, hence any form of treatment other than excision of these glands is only palliative. They recommend the following operative technic:

With the patient anesthetized and placed in the lithotomy position, the cervix is caught with a tenaculum and an incision made on each side beginning at the external os, producing a complete bilateral laceration and making anterior and posterior lips. An incision is then made through the mucous membrane of the portio vaginalis of the upper lip encircling the limits of the eroded area. The mucous membrane of the portio is now pushed back for a distance of a centimetre or more if necessary, to secure a sufficient cuff of the mucous membrane completely to cover over the excised area of cervical tissue. Then, while traction is being made on the upper lip, the entire granular area surrounding the upper portion of the cervical canal is coned out with the scissors. All the infected portion of the canal can thus be excised by direct inspection, and there is no necessity for fearing that either too much or too little of the cervical canal will be removed. A suture of No. II chromic catgut on a full curved needle is placed through the previously liberated flap of vaginal mucous membrane. The suture begins at either angle and pulls up this flap in a submucous stitch, this to continue around until the opposite angle is reached. The angle stitch goes through the entire cervix beginning in the cervical canal and coming out through the flap of mucous membrane. A similar stitch through the other angle completes the upper suture. When this suture is tied, the vaginal flap originally liberated is now inverted into the hollowed out shell of the upper lip of the cervix.

Transposition of the Ovary.—T. Tuffier (*Surgery, Gynecology, and Obstetrics,* October, 1924) says that the living ovary is included in the thickness of the uterine muscle, it projects partly into the uterine cavity, and is studded with corpora lutea. The ovarian tissue contains a voluminous cyst of ovular origin and a considerable number of microcysts with graafian follicles. The uterine mucosa, normal throughout, makes a little polypoid projection at the level of the ovarian relief. On microscopic section the chorion is notably hypertrophic and the glandular convolutions of the mucosa are greatly hypertrophied. One is in the presence then of a moderate adenomatous evolution, circumscribed, and of a still benign appearance.

From these facts it is justifiable to transpose an ovary with its pedicle into the uterine cavity in order to preserve menstruation and the possibility of impregnation in women who have undergone double salpingectomy. Sterility due to lesions which are seemingly benign or unrecognized is so frequent that it opens up a possibility for the application of this operative measure.

New "Uterine Shelf" Operation.—H. L. Smith (*Surgery, Gynecology and Obstetrics,* July, 1924) says that the operation as described is a safe one. The bladder, supported by the uterus as a shelf, is permanently retained in its corrected position. The symptoms, whether due to the dragging down or to the irritation of the bladder, are completely relieved in at least ninety-five per cent. of the cases. The best results are obtained, as would naturally be supposed, when the uterus is supported by some sort of intra-abdominal operation. A thorough repair of a torn or relaxed perineum and any complicating rectocele is quite essential. A large measure of relief can be expected even in those cases in which the condition of the patient does not warrant opening the abdomen. The fixation of the uterus as described not only does not in itself produce any discomfort, but many patients have an unexpected feeling of well being. Advanced age seems no bar to the operation.

Surgical Treatment of Displaced Uterus and Vagina.—W. Stoeckel (*Zentralblatt für Gynäkologie,* June 28, 1924) uses the following technic in the various displacements of the uterus and vagina:

In cases of uncomplicated retroflexion of the uterus, when there is backache, hemorrhage and secretion as a result of circulatory congestion, he uses the Fritsch pessary and, possibly, the Alexander-Adams operation; if the retroflexion is fixed the changes in the adnexæ should be treated—the chronic type with diathermy. The best operative procedure is the Baldy-Franke operation.

In vaginal plastics he uses as a routine interrupted sutures in place of the isolated suture of the levator, which is an unanatomical procedure, and also the "deep" Lawson-Tait method, less buried, but deeper and more penetrating sutures. The interposition operation gives good results when the anterior vaginal wall is sufficiently stretched. Fixation to the promontory gives equally good results even though the ultimate results are not permanent. The tendency to ileus is avoided either by fixation of the entire uterus posteriorly or by the opposite procedure of forced anteflexion of the body of the uterus by vesicofixation.

Stricture of Female Urethra.—A. S. Pugh (*Annals of Surgery,* May, 1924) presents several cases with the following conclusions: Stricture of the urethra in women is common. The principal cause is a gonococcus infection. The pathology is quite similar to that of urethral stricture in the male. Its most common location is at the external meatus. Most common symptoms are, frequency, urgency and dysuria. The diagnosis may always be established by olivary tip, or bulbous bougies. Prognosis is good in soft infiltrations, while in hard infiltrations it is doubtful. Treatment is best carried out by the use of gentle dilatation. Operative procedures are always to be avoided if possible.

Joint Affections Due to Ovarian Insufficiency.—C. Menge (*Zentralblatt für Gynäkologie,* July 26, 1924) calls attention to the frequently occurring involvement of the joints of the knee and the more rarely occurring involvements of the shoulder, fingers, or the cervical vertebræ, with stiffness or pain, or both. These are often induced by röntgen exposures or during the menopause, associated with amenorrhea. The arthropathy is usually symmetrical and persistent, but it disappears in time without any treatment. This disease picture has been described as bilateral, symmetrical, senile arthritis, but it is really due to insufficiency of the ovary after ovariotomy. The treatment recommended is salt water bathing.

Erythrocyte Sedimentation Test, Especially in Certain Obstetrical and Gynecological Conditions.—O. Burckhardt-Socin (*Schweiberische medizinische Wochenschrift,* July 31, 1924) states that the blood picture must always be taken into consideration in the proper estimation of the rapidity of the sedimentation of the erythrocytes, because anemias, *per se,* cause acceleration of this test. The author carried out this test with special attention in very early cases of osteomalacia and found it positive except in two cases, in which an abnormally high erythrocyte count retarded the test. In these cases of beginning osteomalacia it is important to look for an increase in the blood calcium. Both of these symptoms receded on the administration of adrenalin, as well as the clinical picture.

Treatment of Fibroids of the Uterus.—Cuthbert Lockyer (*British Medical Journal,* June 14, 1924) believes that in fifty-five per cent. of all fibroids of the uterus no treatment whatever is needed. In the remaining forty-five per cent., thirty-five per cent. require removal (myomectomy), leaving ten per cent. to be dealt with by radium. This is equivalent to stating that the field for operation is from three to four times as great as that for radiotherapy. The author considers the use of radium as an alternative to hysterectomy. Surgery and radiotherapy may be run tandem—but to radiotherapy is assigned a very subsidiary status.

Differential Diagnosis of Pelvic Exudate and Pelvic Tumors.—Hermann Jentter (*Zentralblatt für Gynäkologie,* May 3, 1924) recommends the use of percussion of the anterior spine of the ilium for the purpose of differentiating pelvic exudate and pelvic tumors. His experiences lead him to believe that the following conclusions are justified: 1. Percussion of the anterior spines of the ilium normally give a high tympanitic tone. 2. Intraperitoneal exudates, tumors of the major and minor pelvis situated intraperitoneally and adnexal tumors do not change the percussion note of the spines of the ilium. 3. Exudates and infiltrations of the pelvic cellular tissues (parametritis, pelvic cellulitis, paratyphlitis, hematoma of the broad ligament pelvic cancer, etc.) produce a lowered percussion note which may even reach absolute dulness.

Adenomyoma of Rectovaginal Septum.—M. T. Goldstine and S. J. Fogelson (*Surgery, Gynecology and Obstetrics,* June, 1924) present a series of cases with the following conclusions: Hematomata or chocolate cysts of the endometrial type may develop anywhere outside of the uterus provided the normal ovarian function is present to act as a stimulus. In all of the cases reported there was definite evidence of inflammation varying from a chronic inflammatory process to that in which newly formed granulation tissue was the predominant characteristic. The growth in one case apparently was not a transplant or outgrowth from the uterus but appeared to be a developmental rest because of its isolation and the ease with which it could be enucleated. Later the presence of plasma and mast cells indicated chronic inflammation. These growths are not only interesting from an etiological and histological viewpoint but are of marked clinical significance. Their removal has relieved many distressing symptoms. From the study of this group of cases together with others now under observation, the authors feel that the preponderance of evidence is greatly in favor of R. Meyer's etiological theory that these growths are of inflammatory origin, notwithstanding the fact that the presence of tissue in situations where it is not normally found may cause an aseptic inflammatory reaction.

Blood Platelets in Gynecological Hemorrhages.—Walter Vogel (*Zentralblatt für Gynäkologie,* January 19, 1924) found that the total number of the blood platelets and the relationship between the large and the small forms are normal in gynecological hemorrhages, especially in the so-called essential hemorrhages. The only exception is the rare cases of thrombopenia, in which there is a high grade of diminution in the number of the blood platelets and with it a severe disturbance of the coagulating system of the blood.

Uterine Secretion: Brief Investigation of Its Nature in the Human Being.—Isidor Kross (*American Journal of Obstetrics and Gynecology,* March, 1924) is led to the following conclusion by his experiments: Hematocolpos fluid is thoroughly mixed with the uterine secretion that contains a fibrinolytic ferment similar to that present in the rat, and its fluid nature is due to the action of this ferment. Similarly it can be stated that in the normal individual, the menstrual blood is fluid and it does not clot subsequent to its escape from the uterus and vagina, as a result of the activity of this ferment. Where the menstrual fluid is composed of more or less clotted blood in an individual whose internal genitalia are not the seat of abnormal anatomical changes, it seems proper to conclude in that case that there is a deficiency of the fibrinolytic or thrombolytic ferment.

Etiology of Air Embolism Originating in Uterine Veins.—Isidor Amreich (*Zentralblatt für Gynäkologie,* March 1, 1924) asserts that from the anatomical viewpoint the diameter of the pelvic veins depends upon the condition of the surrounding fasciæ and muscles. They need not be excluded from the external world, but if after delivery large amounts of air enter the cavity of the uterus as a result of any therapeutic manipulation and if then a contraction of the levator ani as well as elevation of the pelvis takes place, there may be a suction effect owing to the dilatation of the lumina of the veins by fixation. The veins involved are the sacrouterine plexus, the hypogastric and the uterine veins.

OBSTETRICS

Basal Metabolism Before, During, and After Pregnancy.—Irene Sandiford and Theodora Wheeler (*Journal of Biological Chemistry,* December, 1924) give complete data on the respiratory metabolism of a normal woman before, during, and for six lunar months after pregnancy. The results agree with those of other investigators in that there is a definite increase in the total heat production during the latter part of pregnancy, in this case beginning with the eighth month, and gradually increasing to the tenth lunar month, when the otal calories for each hour were twenty-five per cent. greater than before conception. There was no increase in heat production during lactation, but rather a slight decrease, probably because of the less active life. There were slight daily irregular variations in the heat production after the reestablishment of menstruation, but none which can be accredited to its influence.

Treatment of Puerperal Eclampsia.—Beckwith Whitehouse (*Lancet,* May 31, 1924) treats puerperal sepsis according to three general principles: 1. Treatment must be started at the earliest possible moment. 2. It is unwise to differentiate between sapremia and septicemia, or again to depend upon the superficial characteristics of the uterine lochia. 3. The patient shall be in surroundings where efficient nursing is possible, and where it is carried out by a properly trained nursing staff.

The local treatment includes swabbing of the vagina, cervix and uterine cavity with large quantities of hypochlorite solution. The uterine cavity is then lightly curetted and a large double drainage tube is introduced into the uterine cavity and carried to the fundus of the organ. The uterus is irrigated with the hypochlorite solution every two or three hours. Curettage in the constant presence of a powerful antiseptic has never done any harm in the author's experience. Curettage must be light and it must be associated with constant irrigation of the uterus; if heavy and employed alone it is undoubtedly dangerous.

The general treatment includes: 1, serum therapy; 2, autogenous vaccines; 3, intravenous acriflavine; and 4, a concentrated and nutritious diet and a liberal allowance of alcohol. In severe cases a one in 250 solution of acriflavine in normal saline solution is given intravenously in doses of twenty c.c. morning and evening.

Regulation of Placental Respiration.—Walther Schmitt (*Zentralblatt für Gynäkologie,* February 23, 1924) reports the results of his transfusion experiments on the surviving placenta. With a very slight content of oxygen in the fetal blood there develops an incomplete oxidation in the tissues and resulting metabolic products and a concentration of the hydrogen ions. These in turn produce a dilatation of the bloodvessels and consequently an increased accession of oxygen, complete oxidation in the tissues, and contraction of the bloodvessels. This is demonstrated by the visible contraction of the bloodvessels after a perfusion with an abundance of an oxygen containing Ringer solution and the relaxation of the bloodvessels under other conditions. The oxygen shows no special effect upon the placental bloodvessels.

Dietary Requirements for Reproduction.—Barnett Sure (*Journal of Biological Chemistry,* December, 1924) presents evidence to show that ether extracts from yellow corn, wheat embryo, and hempseed contain an organic factor, called vitamine E, essential for reproduction. Fertility was obtained on rations carrying commercial olive oil and cottonseed oil, while it was not obtained on rations containing commercial linseed and cocoanut oils. Evidence is brought forth to corroborate the theory that the water soluble B vitamine plays a hitherto unsuspected tremendous role in lactation. Skimmed milk powder, fortified with .2 per cent. ferric citrate, when incorporated to the extent of fifty per cent. in a ration, thus furnishing 17.5 per cent. protein, furnished an excellent quality and sufficient quantity of amino acids for the whole cycle of reproduction.

Plasma Protein Variations in Normal and Toxemic Women.—E. D. Plass and L. Jean Bogert (*Bulletin of the Johns Hopkins Hospital,* November, 1924) found that in twenty-two healthy nonpregnant women in the childbearing age the plasma proteins varied from 6.45 to 7.83 per cent., with an average of 7.04 per cent. During normal pregnancy, the plasma proteins start to fall during the third lunar month, or occasionally even before then, and decrease gradually to a minimum during the sixth month, after which there is a slow rise during the latter months of pregnancy, with the values at the tenth month still somewhat below normal. A further sharp rise occurs at the time of labor and is continued into the first day postpartum, but in the next twenty-four hours the proteins suffer an abrupt decrease, which is maintained for three or four days and is followed by a rapid rise to normal at the end of the first week. Patients with the toxemias of pregnancy have similar variations, but the dilution is more marked, depending largely on the extent of the clinical edema.

Insulin Treatment of Vomiting of Pregnancy.—W. Thalhimer (*Surgery, Gynecology and Obstetrics,* August, 1924) reports three cases and remarks upon the success of insulin treatment with them. He points out several essentials of the insulin and glucose treatment. He says that only those cases should be treated with this method in which there is a severe acidosis. This should be determined, first by demonstrating large amounts of acetone and diacetic acid in the urine, or by demonstrating a blood alkali reserve of forty-five or less. When it has been determined that severe acidosis is present, one thousand cubic centimetres of ten per cent. glucose solution should be slowly given intravenously. The time consumed in giving this amount is four to five hours. One hour after the intravenous infusion has been running, twenty units of U. 20 iletin (that is one cubic centimetre) should be given hypodermically. An hour later ten units of U. 20 iletin (one half cubic centimetre) is given hypodermically. No patient has ever had an insulin reaction after these doses.

In the event of marked improvement in the patient's general condition and of the acidosis not occurring in twelve hours, the procedure outlined above should be repeated, and it is better never to give a dose of insulin to a nondiabetic patient without at the same time administering a proper amount of glucose, either hypodermically or intravenously, since one can only be sure of absorption of the glucose when it is administered by one of these two routes.

While the glucose is running, the patient should not be left alone for a minute and should be seen frequently by a physician; and a sterile hypodermic syringe and a bottle of adrenalin should always be available in the patient's room. If an insulin reaction occurs, from three to five minims of adrenalin should be given hypodermically at once, followed by more glucose intravenously or by carbohydrate food by mouth. If in your clinical judgment the patient is greatly dehydrated at the beginning of the treatment, give two thousand cubic centimetres of one per cent. glucose solution instead of one thousand cubic centimetres of ten per cent.

Renal Tuberculosis During Pregnancy.—W. E. Stevens (*Surgery, Gynecology and Obstetrics,* December, 1924) presents a series of cases that the conclusion may be drawn that pregnant women stand nephrectomy well and that this operation for renal tuberculosis is no more serious for mother and child than nephrectomy because of other pathological conditions of the kidney during pregnancy. Following the removal of a tuberculous kidney tuberculin should be administered, the urine examined at frequent intervals for a considerable period of time, and the patient kept under observation. Pregnancy is permissible if the remaining organ is free from tuberculosis and functioning normally after a period of two or three years.

Fibroids in the Puerperium.—E. W. Fischmann (*Surgery, Gynecology and Obstetrics,* September, 1924) finds that fibroid tumors in the puerperium may cause serious complications, frequently a febrile course. They themselves may suffer changes during gestation and labor and these may progress and even be augmented by secondary infection during the puerperium. When a woman with a fibromyomatous uterus becomes pregnant and goes to term, Cæsarean section with an immediate myomectomy or hysteromyomectomy is the operation of choice. When the myoma is not discovered until during labor or in the puerperium, conservatism should be practised as long as possible.

Syphilis and Obstetrics.—E. Klaften (*Zentrablatt für Gynäkologie,* August 30, 1924) remarks that the obstetrician can make an early diagnosis of syphilis in the newborn in one of three ways: 1, by serological investigation of the blood from the umbilical cord; 2, by the demonstration of spirochetes in the fetal end of the umbilical cord, and 3, by the demonstration of leucocytic infiltration in the umbilical cord and changes in the umbilical vessels, as well as by analogous changes in the placenta. In the absence of a febrile or other chronic disease, as tuberculosis of the mother, the changes in the umbilical cord are to be considered as characteristic of syphilis, especially in association with a positive reaction of the serum from retroplacental blood. These three criteria are signs of syphilitic involvement of the newborn and require antisyphilitic treatment of the child even in the absence of syphilitic manifestations. Furthermore, those children that are born of untreated latent syphilitic mothers, or of mothers who became infected during pregnancy and have been treated only after the appearance of secondary symptoms or in the seropositive stage, should be given prophylactic treatment.

Colon Bacillemia in Pregnancy Without Pyelonephritis.—A. Lemierre and E. Rivalier (*Bulletins et mémoirs de la Société médicale des hôpitaux de Paris,* April 3, 1924) report the case of a woman five months pregnant, in whom an infection suddenly developed, which persisted for ten days and was characterized by repeated febrile movements with severe chills and sweats, occurring several times daily, with a temperature range of 37.4 to 40° C. and intense headache. A blood culture showed colon bacilli. At no time was there pain in the kidney region. The urine never became purulent, but microscopically showed many colon bacilli, granular casts, a moderate number of leucocytes and slight albuminuria. Recovery followed without specific treatment. Stress is laid on the frequent chills and fever as a characteristic feature of colon bacillus infection. As the woman had had a marked fecal accumulation on admission, the bacillemia is believed to have originated from the bowel. In spite of the intensity and relatively long duration of the infection, no severe localization of it in the kidney or its pelvis took place, although the germs passed through the renal barrier and appeared in the urine. The case shows that colon bacillus septicemia in pregnancy is not necessarily followed by renal involvement.

Nonprotein Nitrogen Retention During Eclampsia and Allied Conditions. The Blood Nitrogen Curve in Normal and in Toxemic Pregnancies.—E. D. Plass (*Bulletin of the Johns Hopkins Hospital*, November, 1924) studied the blood of ten nonconvulsive toxemic and seven eclamptic patients, and of seven normal women during labor and the early puerperium, in order to determine the normal variations. Analyses of 182 samples of whole blood and plasma were made. The results of these experiments are grouped in a series of tables. It is concluded that after delivery in normal patients there is a tendency for certain nonprotein nitrogen fractions of the blood to rise, and for the protein of the blood plasma to fall; whereas in patients suffering from the late toxemias of pregnancy these changes are almost invariably accentuated, their extent being determined largely by the severity of the disease. In the latter group, similar but slighter changes can follow medicinal treatment without delivery, a fact which is taken to mean that physiological puerperal alterations cannot be held responsible for the changes, although they may augment the variations appearing when improvement is induced by delivery. By exclusion, a tissue retention process is suggested as explaining the changes noted, although the effect of renal insufficiency is not to be disregarded.

Significance of Ocular Changes Occurring in Association with Preeclamptic Symptoms. — Lloyd Mills (*American Journal of Obstetrics and Gynecology*, March, 1924) asserts that the eyes are involved in more than ninety per cent. of all cases of pregnancy as a result of the physiological enlargement of the pituitary gland, which causes different degrees of contraction of the visual fields by pressure upon the optic commissure and tracts. In the more marked cases more or less retinal venous stasis probably arises from the same origin. A temporary but decided loss of central as well as temporal vision, amounting to practical blindness at times, has also been noted in occasional cases, heretofore classed among the toxemias of pregnancy. No gross renal blood or obstetrical pathology is found in such cases, which probably represents an acute obstructive renal stasis and edema, or the direct effect of relatively excessive pressure upon the optic nerve system, or a combination of these factors. The symptoms in these cases, hitherto assumed to be preeclamptic, of headache, nausea and vomiting, and epigastric and colonic distress, occur often without renal or hepatic disturbance. They probably arise from the local intracranial pressure of the hypertrophied pituitary as well as from greatly increased pituitary function. The separation of symptoms, hitherto considered to be preeclamptic, into those of pituitary origin and those arising out of a genuine toxemia of pregnancy, and an accurate knowledge of the relative importance of each, will be accomplished in a large measure, by systematic examinations of the visual fields and eye grounds of all pregnant women who suffer late in pregnancy from headache, nausea and vomiting, abdominal distress and renal or hepatic disturbance.

Hydrostatic Repositor for Prolapse of Umbilical Cord.—D. Monash (*Surgery, Gynecology and Obstetrics*, July, 1924) offers a new selfretaining repositor which he has used with success in several cases. This repositor is made of fabric reinforced rubber and consists of a hollow elliptical ring and a long tail tube. On one side of the oval is a small pocket to facilitate introduction. The outside measurements of the oval are eight by six centimetres, the central opening being two centimetres less in all diameters. The tube is forty-five centimetres long. The fluid capacity at full distention is about forty cubic centimetres. Distended, the repositor withstands a pressure of three hundred milligrams mercury, which is far above the compressor points of a uterine contraction.

The method of introduction is as follows: With the patient in the usual position with the pelvis well elevated the first step in reposition of pulsating cord is to introduce the flat, collapsed repositor into the vagina and with the fingers or forceps draw the prolapsed loop through the opening in the oval. Then directed by the internal fingers the tip of the uterine sound or uterine forceps enters the pocket on the oval or the upper part of the oval is grasped by the forceps and the second step is the carrying of the repositor and engaged loop into the uterine cavity above the presenting part. The third step constitutes the distention of the repositor with sterile water and tying or clamping the tube. The probe or forceps is now removed and the distended repositor with the trapped cord remains in the space between the small parts and the uterine wall.

The tube when fully distended is still pliable and offers no resistance to the advancing head. The distended repositor with the loop of the cord within has the virtue of mass formation, providing a point of fixation similar to that of a small part upon which the cord can be looped. This is further augmented by the crossing of the planes of the distended repositor and the retained loop. The success recorded, in several instances in which repositors were improvised out of a piece of sponge or folds of gauze, was apparently due to this mass immobilization. These are important factors in selfretention. Failure in manual reposition is indeed caused by this very lack of fixation en masse for the mobile loop of the cord if not carried over a small part of the fetus follows the pathway of the withdrawing fingers and is expressed before the head can occlude the lower uterine segment.

No metal or other stiffening substance is incorporated in the rubber repositor, first, because it is desirable to avoid the danger of injuring the uterine wall, placenta or child and second, because the collapsed repositor is more easily introduced through the undilated cervix and when distended is sufficiently rigid for safe retention within the uterus.

Blood Chemistry During Pregnancy.—H. J. Stander (*Bulletin of the Johns Hopkins Hospital*, May, 1924) bases this paper on the results of routine blood analyses carried out upon fifty-three patients. In the analysis, conditions obtaining in normal pregnancy, as well as in the toxemias of pregnancy, have been analyzed. In normal pregnant women there was a definite tendency toward lower values for both nonprotein nitrogen and urea nitrogen, the averages being 28 and 12.48 mg. to 100 c.c. respectively, as compared with 32.3 and 18.5 mg. to 100 c.c. in nonpregnant women. In cases of persistent vomiting there was an increase in the nonprotein nitrogen and uric acid in the fairly severe cases, with a return to normal as the patient improved. In nephritic toxemia, there is a definite increase in the nonprotein nitrogen, the blood urea nitrogen and uric acid. In eclampsia, the nonprotein nitrogen figure is not greatly altered, but there is a decrease in the urea nitrogen. The uric acid content is markedly increased, while the carbon dioxide combining power remains fairly normal.

Cæsarean Technic.—G. S. Foster (*Surgery, Gynecology and Obstetrics*, May, 1924) presents the following operative technic, stating that the success of Cæsarean section is in direct ratio to the perfection of the technic, and that the procedure herein described has for many years proved satisfactory in every detail.

No narcotic is given to the mother preoperatively as it has seemed markedly to influence early reactionary activity on the part of the child. The child was cyanosed and did not breathe as early, at times requiring artificial respiration.

All Cæsarean patients are fully prepared and draped ready for the incision before any anesthetic is given. For all cases up to the time of delivery of the child and placenta we have used gas oxygen only. This is done to assist the child further in becoming active in the reaction immediately upon delivery. For gas oxygen does not seem to influence the child in any way. Shortly after the gas oxygen is started the anticipated line of incision is thoroughly anesthetized with a half of one per cent. novocaine solution, each layer being carefully covered.

Just as the incision is begun thirty minims of ergotol with one cubic centimentre of pituitrin is injected deep in the thigh muscles.

A rather long median incision extending from the umbilicus to the pubic crest is preferred, as this permits of plenty of room for quick and accurate action. The skin, fascia, muscle, and peritoneum are thus quickly incised. As soon as the abdominal cavity is opened towels moistened with warm saline solution are dropped over the lateral edges of the wound cutting off any danger of apposition of these parts with the uterus or exposure of the intestines. These towels are carefully anchored at frequent intervals about the wound.

The hand is then introduced into the abdominal cavity and the position of the uterus quickly surveyed to make sure that the median line of the uterus is in the same plane as the median line of the body.

The uterus is then incised. A previously unused scalpel is employed for this, as was also done when incising the

peritoneum. The author prefers a moderately high incision believing that it permits of more accurate and quick delivery of the child. No attention is paid to constricting the vessels of the broad ligaments. As the amniotic sac bulges it is quickly opened, divulsed with the fingers, one index spreading each angle of the opening.

The presenting part of the child is then gently grasped and the child delivered, cord clamped and cut, and the baby turned over to the pediatrist for immediate care. The placenta is then carefully delivered by gentle separation of the cleavage line with the pulpy part of the finger tips. It is made sure that every part of the placenta is delivered.

So far in the operation there is very little loss of blood, not over half an ounce. Immediately upon delivery of the placenta the uterus contracts under the influence of the ergotol and pituitrin and all oozing ceases. Clean towels are then quickly draped about the wound and anchored.

The uterus is quickly brought out onto the clean field and all areas mopped dry and the suturing begun, the assistant beginning at the upper extremity and the operator at the lower extremity of the uterine incision, using a long, straight, cutting pointed needle threaded with No. 2 chromic catgut. These sutures are passed through the entire thickness of the uterine wall with the exception of the mucosa. As soon as the sutures are passed they are tied and held both below and above by a second assistant. Thus the uterine opening is held taut and closed. These sutures are passed about a half inch apart and as each succeeding suture is tied and held below and above, the preceding ones are cut. In this way rapid and accurate progress can be made while any bleeding is noticeable by its absence.

After completing this line of sutures, three mattress sutures include both sides of the incision and when tied infold and cover over the first line of sutures and the incision. By so doing the first line of sutures is buried, the suture line strengthened and the uterine wall reinforced.

On completion of the mattress sutures all areas are fully dried, special attention being given the space of Retzius and the vesicocervical superior plane. The uterus is then replaced in the abdomen. Following this, the peritoneal edges are quickly picked up at various points and made ready for closure. In closing the peritoneum a continuous mattress suture of No. 2 chromic catgut is used locking each third stitch by a half hitch. By this method rather than by suturing the raw edges of the peritoneum together, the marginal area for about a half inch is sutured to the uterus about the infolding line of the latter. By so doing the suture line of the uterus remains freely exposed and the peritoneum adheres to the uterine wall about it. This suture is made for two purposes. It permits of the formation of an improvised, accessory, suspensory ligament for the uterus and provides for subsequent Cæsarean operations without the direct opening of the abdominal cavity. The abdominal cavity becomes so walled off that subsequent Cæsarean sections are extra abdominal in so far as exposing the intestines or abdominal cavity is concerned. Subsequent Cæsarean sections in cases closed in this manner warrant the continuation of the use of this closure of the peritoneal cavity.

The fascia is closed by a reverse lapping stitch and the skin closed by three through and through silkworm gut sutures and a continuous skin edge linen suture. Just before closing the skin the wound is rinsed with sterile water and after being carefully dried a culture is always made before the skin edges are brought together. This culture taking is carried out not only in Cæsarean but in all closures of previously clean wounds merely as a check upon our asepsis. In Cæsarean cases we also culture the mucosa of the uterus.

Some patients will strain after the child is delivered and will then, but never before this time, require a little ether vapor mixed with the gas oxygen.

In cases where vaginal examination has been made we prefer to leave a short inch gauze wick drain through the cervical canal to the vagina. This is removed on the third or fourth day. If multiple vaginal examinations have been made, and especially by more than one physician; we leave a cigarette drain, which is removed the fourth day, in the lower angle of the abdominal wall incision extending down to the vesicocervical plane and space of Retzius.

Special emphasis is placed on the method of reinforcing the uterine incision and the establishment of an extraperitoneal route for subsequent Cæsarean sections.

BLOOD AND LYMPH GLANDS

Effect of Administration of Calcium Salts on Inorganic Composition of Blood.—Harald A. Salvesen, A. Baird Hastings, and J. F. McIntosh (*Journal of Biological Chemistry*, June, 1924) undertook the present investigation to study the effect of oral and intravenous administration of calcium salts on the acid-base equilibrium and the inorganic constituents of the blood, and to attempt to trace the fate of intravenously introduced calcium chloride. The experiments were performed on normal dogs, and on two nephritis patients, to whom calcium salts were administered as therapeutic agents to produce diuresis. The results show that the ingestion of calcium chloride may produce a severe, uncompensated acidosis in dogs and human subjects, due to a replacement of HCO_3 by Cl in the blood, and as a result of absorption from the alimentary tract of the Cl of $CaCl_2$ without the Ca. An actual loss of base from the blood and a failure to adjust the CO_2 tension to the lowered bicarbonate was also observed. Calcium lactate, given orally, produced no characteristic change in the blood in two cases of Bright's disease with low blood calcium and low protein. The intravenous administration of 0.5 to 1.10 gm. of calcium chloride had no effect on the acid-base equilbrium of the blood, but caused a moderate rise in the phosphates. The injected calcium left the blood in three to six hours. There was no increase in the daily excretion of calcium in urine and feces for six days after the injection.

Further Studies on Blood Grouping.—C. G. Guthrie and J. F. Pessel (*Bulletin of the Johns Hopkins Hospital*, February, 1924) state that temperature is an important factor in isohemagglutinin reactions. Agglutinative titre is higher and agglutination occurs more rapidly at icebox than at body temperature. More isoagglutinin is required to cause clamping at body than at icebox temperature. Thus an amount of agglutinin sufficient to cause marked agglutination in the icebox may escape recognition in tests made at 37° C. or at room temperature. Isohemagglutination tests should be carried out at a constant temperature. That of 15° C. is recommended. Time is also a factor to be considered in agglutination by diluted sera. It is probably of similar importance in tests with weak undiluted sera. Preparations that have stood from one to two hours are considered within the limit of safety.

Variations in the Acid-Base Equilibrium of the Blood in Disease.—Victor C. Myers and Lela E. Booher (*Journal of Biological Chemistry, April, 1924,*) reports the pH of venous blood plasma of normal individuals at rest and at sea level between 7.35 and 7.43 regarding figures below and above these ranges as definitely abnormal. The data in two hundred cases support the conception, advanced by Van Slyke, and conditions of acid-base variation have been met which fall into each of the nine areas described by him. Alkalosis is said to be a condition often overlooked, and sometimes confused with acidosis by the clinician. It may occur after the administration of sodium bicarbonate, following x ray treatment, prolonged periods of persistent vomiting, in the course of fevers, and possibly in gall bladder disease. Contrary to the opinion formerly held, patients may live for a comparatively long period with low pH values.

Clinical Significance of Pathological Changes in Hodgkin's Disease.—Dougles Symmers (*American Journal of the Medical Sciences*, March, 1924) divides this disease into two groups of cases: 1. Those in which the changes are confined to the lymphoid structures, i. e., to the lymph nodes proper and to residual lymphoid foci in the spleen, in the walls of the portal vessels, and in the interstitial tissues of the lungs, kidneys, bone marrow, subcutaneous tissues, and serious membranes. 2. Those with the same sort of changes in the same localities, but with in addition infiltration and destruction of muscles, bloodvessels, serous and mucous membranes, erosion of bone and mechanical replacement of solid viscera. It appears that we must relinquish the conception that Hodgkin's disease is most commonly shown by enlargement of the lymph nodes of the neck. In the series studied by Symmers the disease displayed itself as an enlargement of the abdominal lymph nodes, or of the abdominal and thoracic nodes in combination ten times more frequently. It is a fact of clinical value that enlargement of the axillary nodes is secondary to involvement of the thoracic or cervical nodes, and that enlargement of the inguinal nodes is secondary to involvement of the abdominal nodes. These observations suggest that the provocative agent does not enter through the skin, but

exclusively through mucous membranes, and probably only through the mucous membranes of the gastrointestinal tract, although the respiratory tract cannot be excluded. It is significant that in this series there was not a single case in which enlargement of the peribronchial nodes could be implicated other than as an associated phenomenon, never as the predominant focus. The brunt of attack is borne by the lymph nodes of the abdomen, thorax, neck, axilla and groin and by the auxiliary lymphoid system, while the lymphoid follicles which lie in the submucosa of the gastrointestinal, respiratory and urinary tracts practically always escape intact. Evidence is offered to show that Hodgkin's disease may reveal itself the most prominently in organs other than the lymph nodes, that enlargement of the spleen, thymus, or liver may be the predominant feature, the associated lymph-node enlargements assuming a place of secondary importance.

According to Symmers this disease is divisible clinically and anatomically into five groups: 1. Hodgkin's disease of the regional lymph nodes: a, predominant involvement of the abdominal nodes; b, of the abdominal and thoracic nodes in combination; c, of the nodes of the neck. 2. Predominant involvement of the thymus. 3. Predominant involvement of the spleen. 4. Predominant involvement of the liver. 5. a, Axillary involvement (sequential to cervical or thoracic lymph node enlargement); b, inguinal involvement (sequential to abdominal lymph node enlargement).

The skeletal muscles may be extensively destroyed by tissue of the same sort as that in the lymph nodes. The bone marrow may react in at least two different ways: It may show hyperplastic changes, particularly in the eosinophiles and eosinophilic myelocytes, or it may be replaced by tissue of identical composition with that of the diseased lymph nodes. Evidence is presented which tends to show that in the reactions in the lymph nodes and in the bone marrow there is a certain parallelism between Hodgkin's disease and chronic myelogenous leucemia. This suggests that the two are fundamentally related and that they probably represent different quantitative responses to the same type of provocative agent. Hodgkin's disease is an affection of the hemolyticopoietic apparatus. Its histogenesis is determined 1, by preliminary hyperplasia of lymphoid cells in various parts of the body, and by the discharge of mononuclear and multinuclear giant cells from the bone marrow, with or without eosinophiles and eosinophilic myelocytes, and their arrest by the hyperplastic lymphoid depots in pursuit of their function as filters, the fibroplastic reaction in the recipient tissues representing a mechanical process designed to support the excess of cells by which they are burdened.

Chemical Blood Analysis in Asthma, Hay Fever and Allied Conditions.—Maximilian A. Ramirez, A. V. St. George, and R. L. Moses (*Journal of Laboratory and Clinical Medicine*), determined the nonprotein nitrogen, sugar, and plasma chlorides in forty-one patients with asthma, hay fever and allied conditions before starting treatment with either vaccines, food protein and diet, pollens, etc., and after its completion. In these conditions there was a relatively high plasma chloride content of the blood, and to a less extent, a rise in the sugar and nonprotein nitrogen, the latter two especially in the nonallergic type of asthma cases with a long standing associated bronchitis. A definite statement that treatment caused a marked change in the chemical constituents of the blood is impossible, but the tables show some diminution in the constituents.

Histopathological and Blood Studies with Silver Salvarsan.—C. W. Hooper and C. N. Myers (*Journal of Laboratory and Clinical Medicine*. December, 1924) undertook this work to study the retention and elimination of silver following repeated intravenous administration of silver salvarsan. No evidence was obtained to show that repeated intravenous administration of silver salvarsan to rabbits in doses of ten mg. to the kilogram (equivalent to a clinical dose of 0.6 gram) or 66.7 milligrams to the kilogram (equivalent to a clinical dose of 4 grams) produces any severe tissue alterations. In all the rabbits that received repeated intravenous injections of 66.7 milligrams silver salvarsan to the kilogram the silver granules were deposited in the Kupffer cells of the liver, rarely in the liver cells proper, and frequently in extracellular groups between the liver cell columns and in the periportal connective tissue. The bone marrow in proportion to its size contained even more silver than the liver, and silver granules were also found in the spleen pulp, interstitial tissue of the kidney, and the tunica propria of the stomach and small intestine. In regard to the effect on the blood, anemia was not produced in any of the eight experiments. The majority of the animals showed a gradual increase in hemoglobin and red blood cells. The white blood cells and differential counts remained within normal limits.

Splenomegaly with Hyperleucocytosis.—M. E. Alexander (*Journal of Laboratory and Clinical Medicine*, September, 1924) reports the clinical and pathological findings of a case of splenomegaly, resembling the cases described in the literature in the past few years as "splenomegaly with hyperleucocytosis." The cases described by other authors are reviewed, and a detailed postmortem study of Alexander's case is given. From the evidence presented, he does not believe that there is any justification to consider these cases as a new clinical entity, but rather he classes them as atypical forms of myelogenous leucemia.

Factors Concerned in the Polycythemia Produced by the Subcutaneous Injection of Epinephrine.—Charles W. Edmunds and Erwin E. Nelson (*Journal of Experimental Medicine*, January, 1925), state that the subcutaneous injection of epinephrine in doses of one mg. to the kilo brings about a polycythemia, an increase in reticulocytes, and an increase in young forms of polymorphonuclear leucocytes. The polycythemia is no doubt partly a concentration phenomenon, but the presence of these young cells in increasing numbers is believed to be evidence that there is at the same time a discharge of cells from the bloodforming organs, due to the effect of the drug upon them. A similar effect is obtained by continued stimulation of the peripheral ends of the cut sciatic nerves in the curarized animal.

Nontuberculous Granulomatous Lymphadenitis.—G. H. Hansmann (*Surgery, Gynecology and Obstetrics*, July, 1924) denominates this disease a clinical and pathological entity. The article deals with a nontuberculous granulomatous lymphadenitis which is a clinical and pathological entity. The infective agent enters through the skin or mucous membrane and leaves a very small, nonpainful lesion which may persist for several months. The accompanying lymphadenitis is extremely chronic, finally leading to periadenitis and sinus formation. The two diseases that give difficulty in diagnosis are tuberculous lymphadenitis and climatic bubo. The only way to rule out tuberculosis with certainty is by animal inoculation. Climatic bubo is by some authors considered an identical disease. There are some striking differences in the clinical history and pathology in these two diseases.

The bacteriological procedures and animal inoculation have yielded no suggestion as to the etiology. As far as is known the material is not pathogenic for animals other than man. Surgery, which aims at the removal of the affected glands and periglandular tissue when involved, leads to prompt recovery.

The Blood and Blood Picture at High Altitudes.—W. Knoll (*Schweizerische medizinische Wochenschrift*, January 31, 1924) finds that the granular and intermittent flow of blood in the capillaries occurs both at low and at high altitudes to the same extent; it actually increases the number of erythrocytes, but it can be prevented by external measures, whereupon the number of erythrocytes is diminished. The increase in erythrocytes and of hemoglobin and the diminution of the viscosity of the serum and the refraction values are compensatory processes. Even healthy individuals may show an isolated increase of erythrocytes alone or of the hemoglobin alone at high altitudes. As a rule high erythrocyte values correspond with relatively diminished hemoglobin values. This occurs in tuberculous patients in proportion to the time of the accommodation, but about twenty-four per cent. of the cases show a primary increase of the hemoglobin without an increase of erythrocytes (pernicious type). In a certain group of severe cases of tuberculosis (with rapid extension of the process over extensive pulmonary areas, pneumothorax) the erythrocytes and hemoglobin values are greater than the medium values in healthy individuals. The reduction of the respiratory surface of the lung is compensated for by the increased surface of internal breathing. In cachectic cases a reduction of the erythrocytes and the hemoglobin is usually demonstrable, which is always a prognostically unfavorable sign. The erythrocyte and hemoglobin values in cases of surgical tuberculosis that were treated with heliotherapy are far below those of the average in the first, second, and third stages, in spite of good results with sanatorium treatment.

EXPERT TESTIMONY AS TO DIRECTION FROM WHICH SHOTS FIRED HELD INADMISSIBLE

In a murder case a medical witness for the state, who had testified to the different wounds on deceased's body and that a bullet entered the upper part of the arm, was asked the following question by counsel for the state: "From your experience in examining wounds of that sort and character, and as a practising physician, would you say that wound indicated from which direction it was fired, whether from the front or rear?" Over objection the witness answered: "I would say it wasn't fired from the front." Motion to exclude the answer was overruled. The witness had testified that he was not an expert on the question as to the direction from which shots were fired. He was a medical expert only.

Holding that the opinion of the witness was inadmissible, the Alabama Supreme Court said that the matter about which the opinion of the witness was sought was an inference from facts which it required no peculiar skill or particular fitness to solve, and which it was the province of the jury alone to determine. It was proper for the witness to describe the wounds, and for the jury to draw the inference as to the direction from which the shot was fired. Humber v. State (Ala.) 99 So. 68.

CONSTRUCTION OF PHYSICIAN'S CONTRACT TO TREAT INJURED EMPLOYEES

The Alabama Supreme Court holds, American Mut. Liability Ins. Co. v. McDiarmid, 99 South, 849, that under a contract between a physician and surgeon and an insurance company by which the former agreed to treat, on the insurance company's account, all cases of accident occurring to employees of a manufacturing company, arising out of their employment until the injured employee should be able to return to work for compensation, at the rate of 17½ per cent of the premium paid to the insurance company, the surgeon could not recover, in addition to this agreed on compensation, payment for the continued treatment, after the contract had expired, of employees injured before its expiration.

INDICTMENT FOR PRACTISING WITHOUT LICENSE UNDER WEST VIRGINIA STATUTE

The West Virginia Supreme Court of Appeals, State v. Morrison, 123 S. E. 678, holds that an indictment which charges that the defendant "without having first complied with sections 9, 10, and 11 of chapter 150 of the Code of West Virginia, governing the applicants and issuing certificates to practice medicine and surgery in the state of West Virginia, and without having first obtained a state license so to do as required by the laws of the state of West Virginia, did unlawfully practice medicine and surgery as defined in chapter 150, section S—A, Barnes' West Virginia Code Annotated 1923, "is not subject to demurrer because it does not point out the particular acts done by defendant. Upon demurrer to such an indictment the court will not determine whether one who, without the license prescribed, practises chiropractic, does or does not come within the inhibitions of the statute, since the particular acts performed by him in the practice of his profession are not described. The court is not, upon demurrer, called upon to determine what particular acts constitute the practice of medicine and surgery, and it would be improper, upon the present record, to determine whether the practice of chiropractic, without the license or certificate prescribed, by the statute, is inhibited.

ALABAMA STATUTE HELD AS NOT DISCRIMINATORY AGAINST CHIROPRACTORS

The Alabama Court of Appeals holds, Jackson v. State, 99 South. 826, that under the laws of the state any person who treats, or offers to treat, disease of human beings, by any system of treatment whatsoever, must obtain a certificate of qualification so to do from the state board of medical examiners, and the treating or offering to treat diseases of human beings without having obtained a certificate of qualification from said board is a misdemeanor (Acts 1915, p. 661), and this applies to the chiropractor as well as to any one who treats, or offers to treat, diseases of human beings by any system of treatment. In other words, under the present law the privilege of engaging in the calling or profession of treating or offering to treat, disease of human beings by any system whatsoever, is denied to all persons who have not obtained the required certificate of qualification from said board.

This statute, it is held, is not unconstitutional, but is a valid exercise of the police power, having as its purpose the protection of the public. It "is not discriminatory, as the authority of the state board of medical examiners to issue certificates of qualification is not limited to those who desire to enter the profession as homeopathic doctors, but extends to all schools or systems of treatment. Therefore the chiropractor is not excluded or discriminated against under the provisions of this statute, for he has the same right to apply to the board for the required certificate of qualification as has the osteopath or homeopath, and if the necessary certificate of qualification is awarded him, there is nothing in the law that denies him the right to pursue his method known as the chiropractic system of treatment."

Where, in a prosecution for treating diseases of human beings without license, the state has offered testimony showing that the defendant treated diseases of human beings, the burden is held to be on the defendant to show that he has obtained the certificate of qualification required by law.

ESSENTIALS OF DYING DECLARATIONS

It is essential to the admissibility of dying declarations that at the time they were made the declarant should have been in actual danger of death, that he should then have had a full appreciation of his danger, and that death had ensued. Dying declarations, to be admissible, must relate to the facts and circumstances of the shooting, and are admissible to prove any relevant fact embraced in the res gestae of the killing, if the deceased would have been authorized to testify to it if he had lived and been present at the trial. Dying declarations are limited to the act which caused death or the crime and the res gestae. Humber v. State (Ala.), 99 South, 68.

SICKNESS FROM INHALING EMERY DUST HELD NOT COMPENSABLE

The Indiana Appellate Court, Moore v. Service Motor Truck Co., 142 N. E. 19, holds that an employee in charge of emery wheels in the grinding department of a motor truck factory who knew that the air in which he worked was impregnated with emery and metallic dust; that it was passing into his lungs and bowels; that it had made others sick and was injuring him from day to day, and who ultimately suffered from a sloughing of the lining of his bowels, leaving raw areas, could not recover under the Workmen's Compensation Act as for the result of an accident, his condition not being an unlooked for mishap or untoward event not expected.

Surgical Injuries of the Ureter

P. BROOKE BLAND, M.D.
Philadelphia, Pa.

A symposium on surgery of the ureter was held at the annual meeting of the Medical Society of the State of Pennsylvania, in Pittsburgh, October 4, 1923. I read a paper on The Treatment of Accidental Occlusion of the Ureter, reporting six personal cases. Since presenting this paper I have had the unhappy experience of encountering another case and this I regard as a legitimate text for an additional contribution.

In the original article the various phases of surgical injury of the ureter were considered. In preparing material for the paper the large number of cases reported in the literature indicated that surgical accidents of the ureter were by no means uncommon. Most writers seem to regard operative trauma of the ureter as exceptional and nearly all are in accord in believing unilateral injury unusual and bilateral damage exceedingly uncommon.

Only a few papers have been written on ureteral damage which have reviewed the subject in more than a superficial way. Most of the contributions have been in the form of case reports with an expression of personal views relating to special features of ureteral damage. The large number of cases previously recorded have not been thoroughly correlated.

Recently a few papers have appeared, notably one by Herman, recording a series of twenty-four bilateral cases. Barney has recorded sixty-two cases, including thirty-two reported by Sampson in 1902. Oeconomos has chronicled a series of 159 cases.

In collecting material for this paper, I was able to collect from the literature 316 cases and I gathered 125 additional cases from men active in abdominopelvic surgery. These give a combined total of 441 cases, the largest number compiled in a single paper thus far presented. Even with this large array of collected cases, there are probably a large number of others which have not been recorded and still others which have not been recognized. In the 316 cases found chronicled in the literature, fifty-eight were bilateral, including the twenty-four cases reported by Herman, and 258 were unilateral. To these 316 cases we have reports of fifty-one representative surgeons from various parts of this country. Nine of these men assert that they have had no personal cases, but have seen cases in consultation or knew of cases in the practice of their contemporaries. Forty-two surgeons reported 125 cases, ranging from one to eight with an average of three each. Of this number twenty-three were bilateral and 102 were unilateral. These combined aggregate 441 cases, of which eighty-one involved both sides and 361 one side alone. This collection we believe represents the largest number of cases hitherto recorded. The previous largest collection, 159 cases, being reported by Oeconomos in 1914.

Despite the prevailing belief that ureteral damage is rare, I believe it to be one of the most, if not the most frequent, as well as the most serious accident of pelvic work—frequent because confirmed by the large number of cases I have been able to collect; serious because often associated with kidney destruction, and still more serious because it carries a higher mortality than any other accident of major pelvic surgery.

Owing to the present mode of exposing the ureters by free dissection—the technic usually followed in extensive pelvic operations today—ureteral damage is perhaps not so frequent as it was a decade or two ago, an era when "suppression of urine" was not infrequently cited as a cause of death. Probably certain percentages of deaths following hysterectomy, both vaginal and abdominal, and extensive pelvic operations in general, in which the cause of death was ascribed to suppression of urine, were actually due to ureteral occlusion. Postoperative urinary suppression in the true sense, heretofore occasionally designated as a cause of death, now rarely is mentioned. I am extremely doubtful of the existence of this trouble as a postoperative entity. Even the case of anuria and death following unilateral ligation as recorded by Barney, may have had its origin in injury of the opposite ureter or in preexisting renal disease. Barney, in unilateral experimental ligation of the ureter performed upon thirty-seven animals, found that the renorenal reflex, as evidenced by anuria, did not occur in a single instance.

Ureteral damage is most frequently inflicted during the performance of some type of deep pelvic surgery and the two operations most frequently responsible are abdominal and vaginal hysterectomy. The vaginal method of extirpating the uterus exacts a definite toll, but not to the extent it did a decade or two ago. Radical abdominal hysterectomy, especially for carcinoma of the uterus, is the operation

Copyright, 1925, by A. R. Elliott Publishing Company.

most frequently responsible for the injury today. However, since the advent of radium in the therapy of uterine cancer, the extended abdominal operation is slowly but surely finding its place in the category of obsolete methods. With the wider use of radium ureteral damage as a sequel of pelvic surgery will become progressively less frequent.

It is quite safe to say that every deep pelvic operation carries the potential hazard of ureteral injury. The anatomical position of the tube exposes it to unusual jeopardy in nearly all extensive operations performed within the dependent part of the pelvic cavity. No section of the tube, however, is free from danger. Even in the renal region, damage has been inflicted, either as the result of ligation or clamping. The section most frequently exposed to the vicissitudes of surgery is that extending from the brim of the pelvis to the vesicoureteral junction. On the right side even the section above the pelvic brim in the region of the appendix has been injured. In the midsection damage has been sustained during the course of operations upon the Fallopian tubes for inflammatory disease and also in operations for broad ligament cysts and for retroperitoneal neoplasms, both benign and malignant, though injuries of the tube above the cervical section are rather exceptional. It is the cervical area which is involved most frequently by far in accidental damage and it usually results from the application of clamps or ligatures to the uterine vessels, during the course of hysterectomy for cancer. The cervical section is also the most frequent site of injury in vaginal hysterectomy, especially as performed by progressive ligation or clamping from below upward. In the modern method of extirpating the uterus through the vagina by inverting the fundus and ligating the broad ligaments with their vessels from above downward accidental damage, while it occasionally does occur, is not nearly so likely as in the technic formerly in vogue.

SIDE AFFECTED

In studying the tables accompanying this paper, it is interesting to observe the relative frequency of injury of the two sides.

In the combined total of 361 unilateral cases the right side was affected in 132 cases and the left side in 132 cases. In ninety-seven, the side injured was not mentioned.

From these figures one is justified in assuming that ureteral damage is about equal on the two sides. In addition to the unilateral cases there were eighty-one cases in which the injury involved both ureters.

In this connection it may be of interest to report my personal experience. During the past fifteen years I have injured the ureter on six different occasions and I have assisted Dr. E. E. Montgomery in performing a double ureterovesical anastomosis for bilateral ureteral occlusion.

Case I.—The first patient on whom the injury was inflicted, was operated upon for advanced carcinoma of the cervix. The operation was performed fifteen years ago. A radical abdominal hysterectomy was performed. Ten days subsequently a ureterovaginal fistula was discovered. Examination disclosed the right ureter severed. Three months after the primary operation, the vaginal vault, in accordance with the plan of the late Dr. X. O. Werder, was converted into a part of the bladder cavity. The patient made a complete recovery and is living and well today.

Case II.—This patient was operated upon for extensive carcinoma of the cervix and a radical Wertheim hysterectomy was performed. Two weeks following the abdominal operation, urine escaped into the vagina and a ureterovaginal fistula was found. Examination revealed the left ureter as the seat of trouble. Two months later the abdomen was reopened with the view of implanting the ureter into the bladder or performing a ureteroureteral anastomosis. Owing to the presence of dense adhesions about the ureteral stump, considerable damage was inflicted during its liberation. This, together with obvious signs of infection, led us to abandon the plan of anastomosis. A nephrectomy was performed. Convalescence of this patient was not disturbed. She left the hospital on the twenty-fifth day after operation. She is still living and well.

Case III.—The third patient was also operated upon for carcinoma of the cervix. The uterus was removed in accordance with the plan advocated by Wertheim and the usual course of dissecting out and protecting the ureters was followed. Before peritonizing the cervical stump and the stumps of the pelvic ligaments, the routine plan pursued by the writer of making a final inspection of the ureters, was carried out. This disclosed the right ureter normal. The tube upon the left side, just where it is traversed by the uterine vessels, was found almost completely severed. The severed ends were attached to each other by a ribbonlike band. The tube had evidently been incised with scissors in cutting the uterine vessels. The various methods of correcting an injury of the type mentioned were considered. The choice of operation appeared to resolve itself into a ureteroureteral or a ureterovesical anastomosis. Owing to the small size and undilated condition of the damaged tube, the latter recourse was adopted. The recovery of the patient was not further complicated and she left the hospital at the end of the third week. She survived the operation eighteen months, finally succumbing to recurrent malignant disease. This case emphasized the fact that in spite of every possible precaution ureteral damage may still be inflicted.

Case IV.—In the fourth patient the left ureter was incised, but not recognized, during a hysterosalpingooophorectomy for extensive pelvic inflammatory disease. A ureteroabdominal fistula appeared on the fourth day. The patient died on the sixth day of septic peritonitis.

Case V.—This patient was operated upon for complete prolapse of the uterus. A vaginal hysterectomy was performed. The uterine vessels on the left side retracted and considerable difficulty was experienced in securing them by ligation. In endeavoring to obtain hemostasis the left ureter was pinched with a hemostat or partially occluded in a ligature. Two weeks following operation, urine was discharged from the vagina and a left ureterovaginal fistula was discovered. This patient was kept under observation and at the end of three months the damaged ureter had closed spontaneously. This case occurred quite recently and the patient is reported well.

CASE VI.—This patient also was operated upon for complete prolapse. The trouble was of several years' standing. Vaginal hysterectomy was performed. Considerable difficulty was experienced in controlling the bleeding, owing to vessel retraction on the left side. The bleeding vessels were finally secured by the application of long curved hemostats. These were allowed to remain in position for seventy-two hours. The patient was operated upon in May, 1923.

Dribbling of urine started shortly after the removal of the clamps and continued until July, 1923. She was free from dribbling until August. The trouble then recurred periodically until March, 1924. She was then readmitted to the hospital, and the fistula was found high up in the left vaginal fornix. The trouble was corrected by a high colpoclysis, as advocated by the late Dr. Werder, of Pittsburgh. This method of correction was only partially successful. The patient returned to the hospital in May, 1924, complaining of "slight dribbling." Examination revealed a small opening in the bladder and a persistent ureterovaginal fistula. The vesical opening was closed. The left ureter was exposed through a free abdominal incision and ligated in two places. The patient had a perfectly normal recovery and now is entirely well.

CASE VII.—The seventh patient was operated upon by Dr. E. E. Montgomery for advanced cervical carcinoma. A radical abdominal hysterectomy with wide excision of the parametrium was performed. Both ureters at the site where they are crossed by the uterine vessels were ligated and severed. The accident was not recognized at the time. Complete anuria followed the operation. Thirty-six hours subsequently the abdominal incision was reopened. The stump of the cervix was exposed and the incised ureters liberated and deligated. A double ureterovesical anastomosis was performed. The convalescence of the patient was surprisingly mild. She survived the operation without any urinary disturbance for one year, finally dying from recurrent malignancy.

TYPE OF OPERATION IN WHICH URETERAL INJURY MAY BE INFLICTED

While hysterectomy, either abdominal or vaginal—but more commonly the former—is largely responsible for ureteral injury, there are a great many other surgical procedures on which responsibility may be placed. A tabulation of operations—twenty-four in all—in which the accident has occurred, will be given.

In order of frequency they may be summarized as follows:

1. Radical abdominal hysterectomy (Wertheim's method for cervical carcinoma).
2. Radical vaginal hysterectomy (Shauta's method for cervical carcinoma).
3. Combined vaginal and abdominal hysterectomy for cervical carcinoma.
4. Vaginal hysterectomy (clamp method for uterine conditions other than carcinoma).
5. Total abdominal hysterectomy for uterine myomata, especially if adherent and associated with intraligamentous growths.
6. Operations for the removal of intraligamentary cysts.
7. Subtotal hysterectomy (supravaginal) for myomata, especially if adherent or complicated by intraligamentary neoplasms.
8. Hysterosalpingooophorectomy for extensive pelvic inflammatory disease.
9. Herniotomy, especially if complicated by congenital or acquired malposition of the bladder and ureter (Corliss in 1904, reported eleven such cases, six inguinal and five femoral) (Herman).
10. Operations for the removal of vesical neoplasms.
11. Surgical correction of vesicovaginal fistulæ.
12. Operations upon or in the region of the kidney itself.
13. Poro operation (two cases are recorded in the table accompanying).
14. Operations upon or about the appendix and cecum.
15. Operations upon or about the sigmoid and rectum.
16. Operations for removal of retroperitoneal pelvic tumors.
17. Extensive plastic operations upon the anterior vaginal wall, especially for uterine prolapse.
18. Perforation of the ureteral wall in passing the ureteral catheter. (See case reported by Noble).
19. Operations upon a horseshoe kidney or where double ureters exist.
20. Trauma of the ureteral wall from undue manipulation or from damaging the blood supply, followed by necrosis in various pelvic operations.
21. Kraske's operation for rectal carcinoma.
22. Percy's method of treating uterine carcinoma.
23. Ureteral injury sustained from the application of radium. (Baldwin's case.)
24. Instrumental labor.

The operations in which the accident occurred in sixty-one bilateral cases were mentioned in fifty-eight as follows:

Abdominal hysterectomy	40
Vaginal hysterectomy	6
Supravaginal hysterectomy	4
Percy cautery	3
Pelvic operation	3
Oophorectomy	2

In 258 unilateral cases the operations ascribed as responsible for the injury were:

Abdominal hysterectomy	164
Vaginal hysterectomy	32
Salpingooophorectomy	19
Myomectomy	9
Combined vaginal and abdominal hysterectomy	4
Sacral hysterectomy	4
"Laparotomy"	1
Posterior colpotomy	1
Porro operation	1
Type of injury not stated	23

TYPE OF INJURY

The type of injury is variable, depending somewhat upon the character of the operation. The most frequent forms of injury are: 1, Ligation; 2, incision; 3, excision; 4, necrosis following undue manipulation or cutting off the blood supply.

The injury may involve one or both ureters and it may be partial or complete. Damage has also been inflicted by heat in applying the Percy cautery and partial destruction of a ureteral wall followed the application of the electrothermic angiotribe, as in the case recorded by Fisher. Indirect damage with

necrosis and fistula formation results from undue manipulation and from destruction of the nutrient vessels. Wertheim, in sixty hysterectomies for cervical carcinoma in which the ureters were exposed for a considerable distance, records five ureterovaginal fistulæ, two of which were bilateral. These Wertheim believed represented necrosis from cutting off the blood supply. In some cases a moderate or even a large section of the tube may be completely excised. Radiotherapy also has a place in the etiology of ureteral damage. A case, mentioned by Baldwin, is recorded in this article.

In fifty-two bilateral cases in which the type of injury was mentioned the ureters were ligated, severed, clamped or damaged as follows:

Ligated	34
Ligated and severed	15
Clamped	3

In 258 unilateral cases the operations ascribed as tioned in 207 as follows:

Severed	100
Ligated	48
Clamped	19
Damaged	16
Excised	8
Torn	7
Partially severed	3
Punctured	3
Obstructed by scar tissue	2
Perforated by ureteral catheter	1

CONCLUSIONS

1. From the large number of cases of ureteral damage herewith presented, it is apparent that the accident is a surgical complication of some magnitude and more frequent than generally is assumed.

2. No doubt a certain number of ligations occur which are never recognized and which do not provoke symptoms, though kidney destruction results inevitably.

3. Damage to the ureter may be inflicted in any section of the tube from its renal origin to the vesicoureteral union, though the cervicovesical section is the most frequent site of injury.

4. Ureteral damage may be inflicted during the performance of a wide range of surgical operations. It is most likely to occur during the course of hysterectomy, especially the radical abdominal operation for uterine cancer.

5. Extensive pelvic operations other than hysterectomy may be responsible for the damage, especially those for intraligamentary neoplasms.

6. In most cases the injury is unilateral. In a certain number of cases both sides are affected, the proportion being approximately six to one.

7. Damage occurs with almost equal frequency upon the two sides. In 361 cases, the right side was affected 132 times and the left side 132 times. In ninety-seven cases the side affected was not indicated.

8. As a surgical complication, ureteral damage is responsible for a certain number of deaths, showing a mortality of bilateral cases of 33.3 per cent. and in unilateral cases a mortality of 18.8 per cent.

9. Irrespective of the mortality entailed, ureteral injury is associated with serious local results both immediate and remote, immediate in the formation of urinary fistulæ (twenty-four per cent.), remote in causing inevitable renal destruction.

Local Anesthesia in the Tuberculous Patient*

ROBERT EMMETT FARR, M.D.
Minneapolis, Minn.

Immediately upon arriving at a decision that it is necessary to carry out a surgical procedure upon a tuberculous patient, it is obviously the surgeon's duty to surround the patient with every known, or at least every available safeguard, not only in a general sense, but in a local sense as well, in aiding him to undergo the surgical attack with the least possible reaction. Not only should the patient's resistance be brought to the highest level but, if the surgeon is to meet his obligation to the fullest extent, he must use methods which, while meeting the surgical indications in their entirety, coincidentally reduce the patient's vitality as little as possible and fortify him against the possible inroads of postoperative reactions and complications. While these platitudes are recognized by all surgeons and adhered to by most of them, it is safe to say that only in the types in which surgical intervention may be considered dangerous to life do the majority of surgeons weigh the several factors involved with sufficient care. Indeed one may question the throughness with which many surgeons evaluate the pros and cons of even the most dangerous surgical procedures before they are put into execution. It would seem at least not unfair to ask if every surgeon offers to every handicapped patient every possible means of resisting the potentialities of a lethal outcome, as well as the variations in postoperative morbidity, as they may be influenced by the varying types of surgical treatment which may be instituted in a given case. A possible death, innumerable complications, delayed convalescence, increased expense, and mental and physical suffering, all hold positions of importance often rivalling and not infrequently exceeding the gravity of the condition which demands operation.

All authorities agree that in treating the tuberculous patient who presents a surgical lesion, we are dealing with an individual who is handicapped. It makes no difference whether the particular surgical lesion with which we must deal is of a tuberculous nature or not, we must face the fact that the patient is handicapped to a greater or lesser degree and that in cases in which the surgical lesion is tuberculous convalescence will be retarded beyond the average time. The various factors encompassed by the term "resistance" of the patient will govern the outcome to a large extent.

*Read before Lymanhurst and Parkview Medical Staffs, Dec. 30, 1924.

The methods of building up the resistance of a patient are well known, although it is probable that patients undergoing surgical treatment do not invariably receive their benefits to the fullest possible extent.

As the application of surgical therapy is inherently, for the time being, a reducer of the normal resistance of all patients and especially so of the tuberculous patient, it is our desire to discuss as briefly as possible our conception of some of the means by which the tuberculous patient and tuberculous lesions may be attacked surgically with as slight a lowering of the patient's resistance as is possible in the light of the knowledge of the present day.

We shall leave to others the consideration of the means by which a patient may be brought to a condition of maximum preoperative resistance—although we would stress to the fullest extent its necessity—and discuss more or less specifically the means by which the patient's resistance may be maintained during and after operation.

A number of factors may be considered. Chief among these is perhaps the carrying out of the surgical procedure with a minimum amount of shock. Following this the elimination of all possible postoperative complications assumes an important rôle, and again, a comfortable, early convalescence under auspices which are conducive to increasing the patent's resistance to the highest point.

The ideas embodied in the preceding paragraphs bring us to a consideration of the subject of this paper, local anesthesia in the tuberculous patient.

The use of local anesthesia combined with the technic which its use demands has, in our judgment, few fields where its good offices may be said to be more desirable than when dealing with this class of patients. As stated above, their resistance is usually lowered. When extrapulmonary tuberculosis exists as a surgical entity, it is not uncommonly secondary to or accompanied by a focus in the lungs. It is therefore most desirable to interfere as slightly as possible with the pulmonary function. Our premise is that the resistance of the severely handicapped will be less reduced by the use of this most benign method and that those who are not in so hazardous a condition, but who have two or more foci of infection in the body, are less likely to have their resistance lowered when local anesthesia and a refined technic are used when operating upon them than when they are operated upon under general anesthesia and the technic by which it is usually accompanied.

In considering the question of local versus general anesthesia in the treatment of tuberculous patients one must not overlook the fact that by far the greatest amount of surgery is performed by those who are below the average in surgical ability and under auspices which are far below the ideal and that, if it is admitted that the local anesthesia method is more benign in the hands of the expert, who is usually equipped with the best protective measures that can be afforded under general anesthesia, it is certainly true in the case of those who are not so expert or not so well equipped. A comparison of the incidence of postoperative pulmonary infections following operations upon the mouth and throat when general anesthesia is supervised by experts with that in which it is not so supervised, will serve to illustrate this point, and yet surgeons of world wide repute, who are equipped with every facility for protecting a patient while operating under general anesthesia, are almost a unit in their choice of local anesthesia for the hazardous risk. The reasons for this are apparent. General anesthesia produces its deleterious effect upon the various tissues and organs almost in direct proportion to the length of time and the amount of the drug administered. It is therefore incumbent upon the surgeon to complete an operation when using general anesthesia with the greatest possible expedition. Haste as a rule is conducive to hemorrhage, trauma and incomplete work, whereas with the elimination of haste the converse obtains. For example, we have had the experience of seeing a patient go into collapse following the ablation of adherent tuberculous tubes after an operation which was completed in less than twenty-five minutes under ether anesthesia. We have also performed the same type of operation under local anesthesia upon patients of apparently the same resisting power without any apparent reaction when the time required for the operation was an hour and a half. This experience has been repeated so frequently that we have no hesitation in stating that in our judgment careful, methodical, clean, sharp dissection, mild retraction, the avoidance of hemorrhage and the observing of the utmost respect for the tissues will be rewarded by a reduction in the amount of shock and will hasten the postoperative convalescence. In other words, the patient's resources will be conserved when more careful methods are used.

In order to be more specific one might consider the strain placed upon the pulmonary mechanism under general anesthesia with that obtained when local anesthesia is used. Assuming, if you so desire, that postoperative pulmonary complications are largely embolic in origin, has not the patient who is the victim of a tuberculous pulmonary lesion—no matter what the extent of this lesion may be—a better chance of resisting his infection and reacting from his operative procedure when local anesthesia has been used than if the laryngeal reflexes have been inhibited by the effects of a general anesthetic and the air passages are waterlogged with infectious material which has been drawn into them from the mouth and nose?

It has been long recognized that the assimilation of nourishing food and large quantities of liquids are prime essentials in combating the ill effects of tuberculosis and surgical operations. The fact that the patient with surgical tuberculosis is not compelled to curtail to any great degree his intake of nourishment either during or after operation constitutes an important advantage of local anesthesia.

Although space will not permit a complete discussion of the numerous tuberculous lesions which must be treated surgically, unilateral tuberculous kidney might be mentioned as an outstanding example. Here as in many other conditions the advantages of local anesthesia are manifold. The pulmonary function is not interfered with, nourishment is assimilated in practically a normal manner, local trauma and shock are reduced to a minimum and above all the function of the remaining kidney is depressed to the slightest possible degree. Another outstanding example is in the case of operations for the cure of

unilateral pulmonary tuberculosis. Theoretically, the ideal procedure should be a fractional operation under an intercostal block with novocaine, with a clean dissection, an absence of hemorrhage and the slightest possible embarrassment of the healthy lung. Speed, with its resulting trauma and hemorrhage, plus the inhalation of septic mucus from the trachea are not, in our judgment, compatible with the ideals of modern surgery. The fact that a large percentage of patients survive despite the application of the methods to which we object is hardly sufficient license to warrant their choice.

TECHNIC

The technic of inducing local anesthesia in tuberculous patients differs somewhat from that which we prefer to use in the nontuberculous. Here regional anesthesia is the method of choice. The anesthetic solution should, perhaps, not be injected into tuberculous areas, although as a matter of fact this point has not been definitely proved. Fortunately, conductive anesthesia is applicable to almost every region which must be attacked surgically: the neck, the breast, the thorax, the spine, the testicle and epididymis or the limbs may be successfully orientated from the central nervous system by nerve or infiltration block by any surgeon who is willing to spend a short time in equipping himself with the necessary knowledge and paraphernalia. Even in abdominal tuberculosis the abdominal wall may be anesthetized regionally and after the abdominal cavity has been opened anesthesia by the anterior splanchnic method may be induced.

CONCLUSIONS

In conclusion may I reiterate that, whereas every patient who presents himself for surgical treatment is entitled to every safeguard at our disposal, this is especially true of those afflicted with tuberculosis.

The tuberculous patient should, whenever possible, have his resistance raised to the highest level before being subjected to a surgical operation. Local anesthesia and a refined technic offers the tuberculous patient requiring a surgical operation the best chance of maintaining his already lowered resistance during and following the operative procedure of any method available at the present time.

1645 Hennepin Avenue.

Medical Work in Syria

JOHN W. SHUMAN, M.D., F.A.C.P.
Los Angeles

During the school year of 1922-23 the Medical Department of the American University, of Beirut, Syria, studied five hundred patients in the hospital and thirty-one hundred in the outpatient department. This report deals particularly with the five hundred male and female adult hospitalized patients. The hospital (1) was composed of four buildings of the pavilion type, and is a part of the medical department of the university. The number of beds in use by all departments was 165. Twenty-two beds were allotted to the medical service; these at stress times were supplemented by floor cots.

Each patient was examined by a fourth year, assisted by a third year, medical student, supervised by first assistant, George Khayatt, and reported at the bedside to either myself or the adjunct professor of medicine, Joseph Yennikomshion. The average time each patient spent in the hospital was eleven and one half days. Thirty-six per cent. of the five hundred patients were females and sixty-four per cent. males. The predominance of men may be accounted for by the fact that about two thirds of the Syrians are Moslems; and the Mohammedan women do not accept hospital service as readily as their Christian sisters.

The raising (2) of the general health standard of people thereby increasing their general usefulness and happiness is certainly a Christian act. This is the aim of those who are doing medical missionary work in Syria, for it is fully realized that this elevating act must be done through sanitation and health service to prevent disease; all of which involves housing, labor age, and private and public enterprise, etc., for conserving health.

Twenty-seven patients of the five hundred died. Autopsies were performed on twenty-five, which demonstrates how well the newly organized pathological service of Douglas Cruickshank and our assistants worked in securing autopsies. While autopsies are not popular in any country this is particularly true of Syria, for the burial teachings of Moses are still believed by Moslem and Jew (*Deuteronomy*). During the previous year but three autopsies were held from the same medical service.

Of the five hundred admitted to the hospital, eighty-six were listed as transferred and unimproved; the transferred included those sent to other services and other hospitals. The remaining four hundred and fourteen were charted as arrested, improved, or recovered; the word "cure" was never permitted. For example, a malaria infection was arrested; a focal infection sufferer improved; and when a typhoid fever patient left the hospital convalescing, recovery was charted.

That we were handicapped in our work is readily admitted, most missionary institutions are handicapped. The greatest handicap was the lack of facilities to work out the diagnosis properly. When I went to Beirut the laboratories (aids in diagnostic medicine) were as follows: There was no fulltime pathologist; the hospital bacteriologist was the instructor in the practical course of physiology as well as the adjunct professor of internal medicine (the latter title without duties); the x ray was of an obsolete type nineteen years old, and at so great a distance from the medical building that it was impractical to transport patients to it. But no difficulties were insurmountable and I am happy to

state that the medical school is getting along fast towards an A plus rating.

Uniform history charts and records for all services, like those used in standardized American hospitals, were recommended and introduced. During the previous year, one hundred and eighty patients were admitted to the medical service, against the five hundred herein reported, which helps to demonstrate the growth of the work.

It was not long before we were able to obtain regular Wassermanns, agglutinins, for typhoid and typhus, complement fixation for hydatid cyst, tuberculin, and other tests, from the hospital clinical laboratory. The native doctors and students and most of my colleagues were enthusiastic for the methods of modern medicine, especially the thorough examination (3) of the patient before a diagnosis.

A brief review of the various diseases follows:

MALARIA

Malaria was positively diagnosed in eighty-nine patients by the recognition of the plasmodium in the blood. Often a sunbath or a provocative dose of quinine sulphate was helpful in bringing the organism into the peripheral circulation. Quinine sulphate by mouth in sufficient amounts and administered over a sufficient length of time was effective in arresting all types of malaria (4). The earlier the infection was recognized and proper treatment administered the better were the results.

The types recognized and treated to an arrest were: tertian, sixty-three; quotidian, nineteen; and quartan, seven.

All of these patients had enlarged spleens. After the chills and fever had subsided the spleen decreased in size. I had the opportunity of seeing the spleen of a man who died as the result of pneumonia; the history yielded the fact that he "had just recovered from an attack of malaria prior to the pneumonia"; the capsule of the spleen was greatly wrinkled. Does the spleen enlarge as a pathological part of malaria, or as a therapeutic measure to protect the owner? An enlarged spleen was also recorded on 141 other charts as follows: from an easily palpable spleen, seventy; from one to seven fingerbreadths below the costal margin, seventy-one. Splenic punctures were made and the smears examined in a number of doubtful malaria cases without any positive diagnostic results.

INTESTINAL PARASITES

Raw meat is a common article of food in the native's diet. Pork is not on the Mohammedan and the Jewish bills of fare, which accounts for the rarity of the pork tapeworm. The beef tapeworm is the most common. Our star patient yielded ten heads of this type and seven round worms; he had been admitted for "pleurisy with effusion" and did have two quarts of seropurulent fluid removed from his left pleural sac. He was discharged as improved and recovered. Anemia was a constant symptom in the parasite carrier.

The male fern procurable was ineffective in getting rid of tapeworm. The converse was true of pumpkinseed. Pumpkinseeds were ground up and administered with honey or sugar, after a fast and a purge. Calomel and santonin were effective for killing the round worm. Frequently eggs of both were found in the stool of the same individual. Most of these patients were admitted for other diseases, for example, typhoid, pneumonia, and other conditions. Prior to 1922 the medical service made no attempt to strain the stools for worm heads, most being satisfied to get rid of a few yards of the worm. By many over there, worms and lice are put in the same category, necessary evils. Diagnosed and treated for: tænia saginata, ninety-two; ascaris lumbricoides, fifty; trichocephalus dispar, eighteen; oxyuris vermicularis, six; and tænia solium, two.

FOCAL INFECTION (NONPARASITIC)

This was found and considered an active cause of disease in 198 persons, and eradicated. It was treated as follows: peridental, 160; tonsillar, twenty-eight; frontal sinus and antra, five; and ear, five. The dental department, with Arthur Dray at its head, was an effective factor in caring for the infection referable to teeth.

LUNG AND PLEURAL DISEASES

The patients in which a diagnosis of active tuberculosis could be made at the outpatient department were not admitted to the A. U. B. Hospital. In each of the thirty-four listed below the bacillus was found in the sputum. Three were admitted to the hospital in a dying condition for autopsy instruction; thirty-four were transferred to the fifty bed tuberculosis sanatorium at Shebonyia, the only hospital in Syria where any special attempt is made to care for pulmonary tuberculosis. I note that asthma was diagnosed thirteen times,—I permitted this for no other reason than insufficient knowledge; asthma, like anemia, is a secondary condition and not a disease. The group: active tuberculosis, thirty-four; pneumonia, twenty-eight; bronchitis, thirty; socalled asthma, thirteen; pleurisy, twenty-eight; hemothorax, one; and pneumothorax, one.

DYSENTERY

This term was used to designate that class of cases in which the chief complaint was protracted diarrhea. Fresh warm stools were always examined. Rest, opium, heat to the abdomen by a woolen binder and hot water bottle, and hot liquid nourishment, preferably milk, were most effective as treatment for these cases. That emetin is a specific for the amebic type is unproved (5). It is valueless in the bacillary. For the latter, "serum" is used,—I saw no untoward effect from its use. The list comprised: amebic dysentery, twenty-two; colitis of various types, thirty-five.

CARDIORENAL VASCULAR DISEASES

Briefly the list was:

Nephritis (dry)	17
Nephritis (wet)	14
Valvular heart disease	28
Arteriosclerosis	18
Hypertensive cardiorenal vascular	13
Pyonephrosis	5
Renal calculus	3
Renal tuberculosis	1
Bilharziosis (infected in Egypt)	1
Aortitis (syphilitic)	1

GOITRE

No severe toxic goitres were observed in over four thousand patients, the total of the year's medical work, and but few were mildly toxic. Of the five hundred studied in the hospital there were: adenomatous, six; adenomatous moderately toxic, two; colloid, four, and cystic, one.

INFECTIOUS DISEASES

In treating encephalitis, Rosenow's antiencephalitic serum, which he so kindly sent in February, 1923, was used in three of the acute cases of epidemic encephalitis (6); it seemed to hasten recovery and shorten convalescence. The chronic encephalitis patients were admitted to the hospital for study and teaching purposes only. Typhus came from Turkey (Armenian refugees); they had head and body lice, which were exterminated before admitting the patient to the hospital bed. The sandfly fever and influenza cases were those in which a fever of short duration was the chief objective symptom and received these diagnoses, I fear, rather than the F. U. O. of the British army medical department (fever of unknown origin). I saw no dengue, as it comes in epidemics and this evidently was not its year for appearing (7). The list follows:

Encephalitis epidemic acute	10
Encephalitis epidemic chronic	4
Typhoid fever	8
Typhus fever	6
Sandfly fever	4
Influenza	3
Acute ascending paralysis	1

JOINT DISEASES

It is admitted that practically all of this group should be listed under focal infection: arthritis, various types, eighteen.

LIVER DISEASES

Hypertrophic	18
Atrophic (complicated by ascites)	7
Catarrhal jaundice	6
Cholecystitis	3
Hydatid cyst (operated upon and recovered)	1

BRAIN DISEASES

Apoplexy, thirteen; pituitary tumor (not confirmed by operation), one; hydatid cyst, one; (8).

Neuritis and allied conditions, eighteen. There were twenty-two who received the diagnosis of psychoneurosis only as a transfer term to the Lebanon Nervous and Mental Hospital, where the students had ample opportunity to study them. Insanity is prevalent among the temperamental races of the Near East.

MISCELLANEOUS

Pregnancy	12
Hydrocele	8
Acute gonorrhea	6
Lumbago	5
Hernia	5
Epilepsy	4
Herpes zoster	3
Leucemia	3
Morphinomania	2
Delirium tremens	2
Elephantiasis	2
Appendicitis	2
Lead poisoning (chronic)	1
Osteopulmonaryarthropathy	1
Urethral stricture	1
Chorea (Sydenham's)	1
Hodgkin's disease	1
Sarcoma	1
Ptomaine poisoning	1
Raynaud's disease	1

Of this group the pregnant women were in the hospital for other diseases than complications of pregnancy. In the acute gonorrhea cases the patients (males) were in the hospital for other cause. Many epileptics could have been secured; these were admitted only for teaching purposes. The elephantiasis were women with local manifestations in the leg legs; they were nonspecific; by that is meant not the Falaria sanguinis hominis type of Bancroft. At least the organism was not found, though repeatedly searched for. The myelogenous leucemia patient was a man who came from Constantinople for treatment, with the diagnosis of abdominal cancer. The routine stained blood smear suggested that the mass in the abdomen was spleen. He died from hemorrhage from hemorrhoids. In the lead poisoning case the patient received her poison from hairdye. A male patient had urethral stricture, causing acute retention; he died on the surgical service.

THE MORTALITY LIST

Nephritis (wet)	4
Nephritis (dry)	2
Valvular heart disease	4
Tuberculosis (lung)	3
Pneumonia (bronchial)	2
Pneumonia (lobar)	1
Encephalitis acute epidemic (6)	2
Cerebral apoplexy	2
Amebic dysentery (5)	1
Syphilitic aortitis	1
Hydatid cyst (brain) (8)	1
Myelogenous leucemia	1
Carcinoma (stomach)	1
Acute ascending paralysis	1
Duodenal obstruction by polyp (9)	1

Autopsies were performed on all the above except those dying from acute encephalitis.

For further data on any of these case records the reader is referred to the central office of the American University of Beirut Hospital.

Much more could be written regarding this one year of medicine in Syria; only the high spots have been touched upon so that those interested in improving the teaching and practice of regular medicine here and elsewhere may get a glimpse of the opportunities that our American medical workers have in Syria.

The Rôle of the Electron in X Ray and Radium Therapy

DONALD C. A. BUTTS
Philadelphia

Throughout the years of medical research, dating back through centuries of conquest and development, there has stood out one disease, defiant, and to date, victorious against man's effort in his search for cause, with ultimate goal of a cure. This disease, equally well known and dreaded by profession and laity, was at an early date appropriately termed cancer.

Uniting their efforts against the ravages of this malady are the surgeon, the pathologist, and the radiologist, each armed with his chosen weapon: the scalpel, the microscope, and most powerful of all, the invisible power of the electron, spontaneously generated or emitted by the physical agents of the radiologist, the x ray and radium. Thus to the army of the offense is enrolled the physicist and the chemist.

Each of these representatives of medical research and practice is confronted with his separate and complex problem. The surgeon will ask why two cases of cancer which have come under the power of his scalpel will suffer reversed fates. Both were apparently similar in every detail, both were operated upon with the greatest of care and surgical skill, yet within the allotted time one has demonstrated a complete clinical cure while the other developed metastases and died within a few months.

FIG. 1.—Theoretical structure of radium atom.

The pathologist is able, by examination of a section of tissue removed by the surgeon, to tell whether the excised growth is of malignant or benign character, but he is completely at a loss to tell us why that tissue which he has verified as malignant assumes the arrangement of cells enabling him to diagnose such as cancer. It is indeed unlikely that such a problem will ever be explained by the examination of cells which have been killed and enbalmed during the necessary preparation for microscopic examination. Nor does the pathologist tell us why such tumors possess altered staining characteristics. Here I might say that the pathologist has overlooked, or failed to find the cause of what I believe to be a most important phenomenon. It would indeed be unjust to condemn the pathologist, for such problems are for the physicist and the physiological chemist, those who have been trained to study and explain the structure and function of these minute structures, appropriately termed cells.

The radiologist asserts that the action of his powerful agents are of caustic nature, yet it is evident that he is unable to explain their action, for as time goes on, and more cases are treated under his most careful observation, he finds that many malignant tumors respond to treatment far below a caustic dose, in fact I might venture to say that in the majority of cases better results are obtained without gross destruction, this is without doubt true of superficial lesions. If not of caustic nature, to what property of the x ray or the rays and radiations from radium can we justly assign their acknowledged beneficial action in the treatment of malignant processes? This is a question which is, at the present time, arousing much interest among the scientific x ray and radium workers.

Although the outlined problems are apparently separate and distinct, they can be reduced to one fundamental question, and were one called upon to condense his question to the simplest significance, it would without doubt be one of the following character: "What is the hidden property of the socalled cancer cell which differentiates it from the normal cell? What is the concealed power that gives to formerly normal cells their stimulated proliferative powers, with the resultant formation of the neoplasm? What is the evasive something which gives to the disseminated tumor cell the power to give rise at a distant part of the body to growth similar to the one of which it was formerly a part?"

We of the present day know that our body cells are nothing more or less than aggregations of complex chemical compounds, proportioned and delicately balanced so as to carry out their allotted duties, one does not have to be a chemist to know and understand this. Those of us who have made a special study of physiological chemistry, or, I might say of even the fundamental principles of elementary chemistry, know that chemical reactions, whether carried out within the body cell or in the test tube, cannot take place without ionization and dissociation of the molecules comprising the agents involved. The ionic or electrolytic dissociation theory of chemical reactivity is without question fundamental, and we are forced to accept the reasoning that all chemical change is primarily physical or electrical, and our entire problem is readily reduced to one of biophysics.

For the benefit of any organic chemists taking exception to this statement, I should like to state that the formation of precipitate in the absence of water or current flow is by no means a conclusive argument to the above statement in face of the preponderating evidence supporting such a theory.

From the reasoning just offered it must follow that all functions of intracellular metabolism must first be physical, electrical or dynamical; second, chemical; and third, or as viewed by the pathologist, histological. These changes must, through necessity, occur in the order mentioned, therefore the initial change brought to bear within a cell undergoing malignant transformation must be electrical or biophysical, this brings about the necessary chemical

alteration which in turn, through greatly increased growth factors, develops the structural abnormality viewed by the pathologist.

However simple this may appear, it must not be confused as such. To understand the change and interchange of the molecules which go to make up

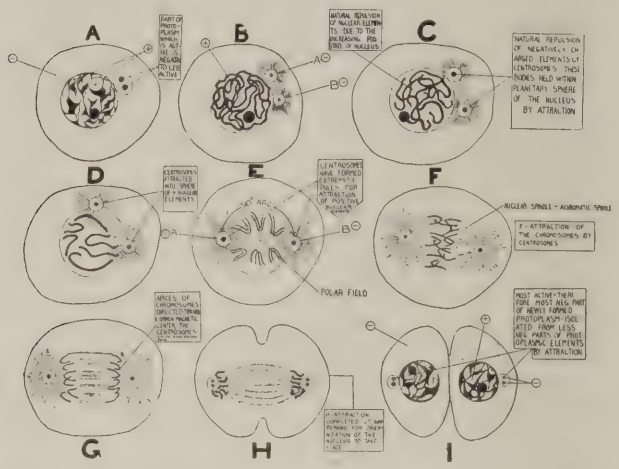

FIG. 2.—Diagrams demonstrating theoretical physical alterations which take place causing the cell to undergo division.

the routine of these complete little chemical laboratories requires a study of a still more basic component, *the atom*.

We, of the present day, know that throughout the disintegration of all the radioactive agents there are cast off, or emitted, definite electrically charged particles, or electromagnetic waves, and it is through the liberation of such positive atoms, negative electrons, or electromagnetic waves, that the decay of the element is brought about and its transformation into a new and totally different element is accomplished. Knowing this, is there any other explanation for the

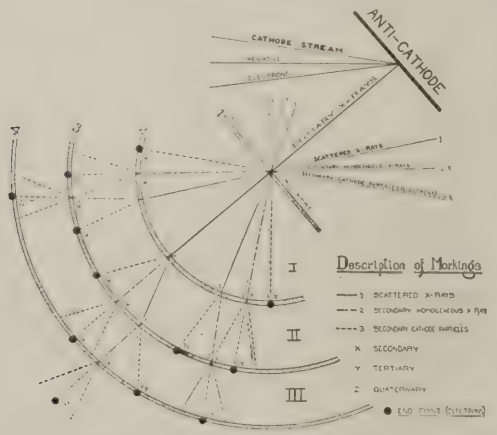

FIG. 3.—Chart illustrating theoretical mode of action of the x ray and necessity of penetrability in the treatment of internal malignancy.

action of these agents other than one of an electrical effect, is there any reason to believe that if unions comparatively stable as those of the elements themselves should be affected by the loss of their atoms, electrons, or electromagnetic waves, that structures so delicately balanced and so fragile as our body cells, should not be far more affected by the action and interaction of such atoms, electrons, or electromagnetic waves, and that by the prolonged and intensified action of these electrical or electromagnetic factors, that the cells coming into direct contact with them must suffer tremendously?

The structure of the radium atom, according to Bohr and other physicists working on this problem, demonstrates a highly complex arrangement of protons and planetary electrons (Fig. 1), yet when the

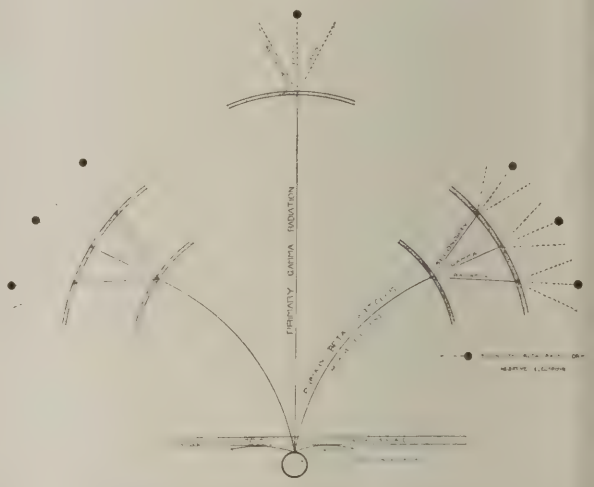

FIG. 4.—Production of negative electrons during the passage of radium rays through the body.

results of their efforts are carefully analyzed and such findings applied to rational physical therapy, I believe the problem can be greatly simplified and utilized so as to bring about results already offering great hopes in our fight against malignant tumors.

Although our subject deals primarily with malignant processes, we must also take into consideration the most fundamental form of cell reproduction, and for this purpose we are forced to consider the natural fertilization of the ovum, for from this union of two

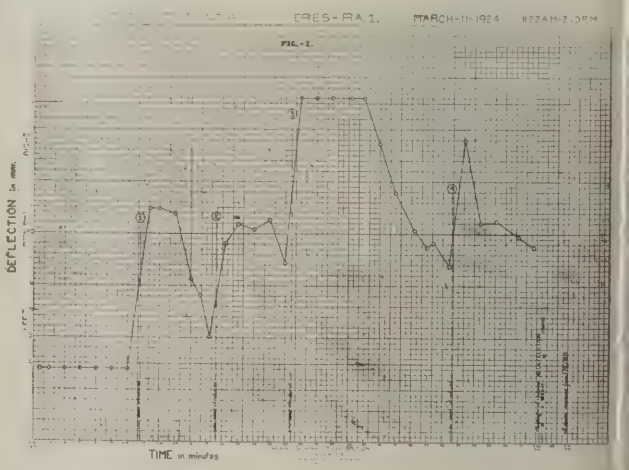

FIG. 5.—Chart illustrating the marked physical effect upon cell potential following the introduction of radium emanation "seeds" into malignant cellular structures. (Note: When coupling wire between animals was removed, no deflection of galvanometer took place).

unit cells (spermatozoon and ovum) our entire bodies are formed and life in its complexities is thereby carried on. Here we have cell reproduction in a far greater excess than is rarely demonstrated in malignancy; here we have cell division induced and stimulated by a known factor, i. e., union of ovum and spermatozoon, here we have two basic components of life which are extremely radiosensi-

tive, and by proper exposure to the rays and radiations from radium or the röntgen tube, sterility of one or both may be brought about, here we have two basic life components of which the chemistry has been quite thoroughly studied and considerable information obtained. Would this not be the logical

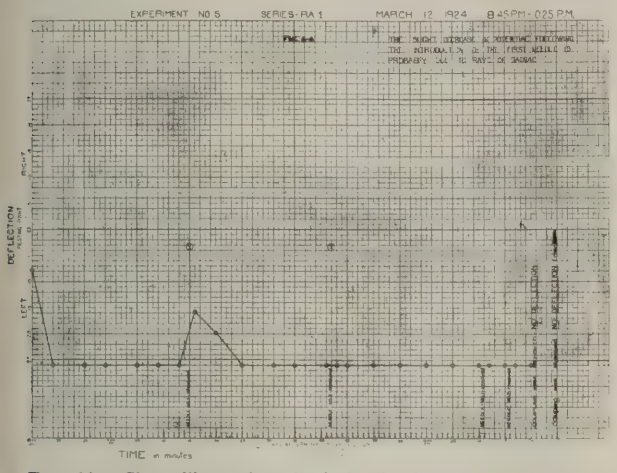

FIG. 6A.—Chart illustrating the lack of effect upon cell potential by the introduction of two, one mg. radium needles.

starting point for an investigation of the mysteries of the stimulated cell division demonstrated in malignancy, and the action of radiations upon such fundamental processes? Is not the study of intracellular metabolism of the individual cell the most promising method of attack, rather than attempting to solve the problem from the study of the gross pathology demonstrated in neoplasia? If we do not study and understand the life and function of the individual cell, how can we hope to explain the processes of anatomical structures, and pathological transformations, which are composed of nothing more or less than huge aggregates of such cellular units?

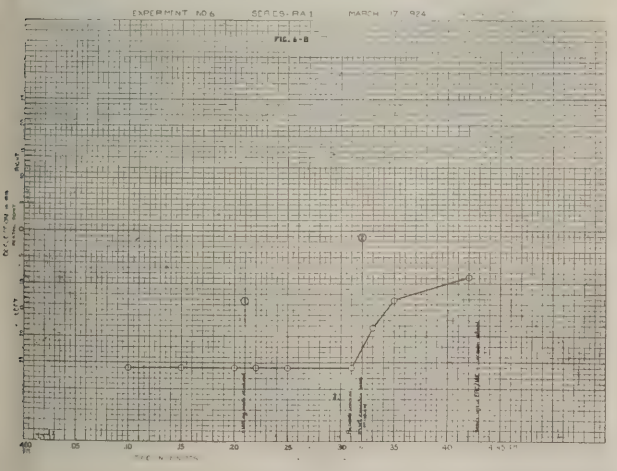

FIG. 6B.—Chart illustrating the lack of effect of gamma radiation and the marked effect upon malignant cellular potential by beta radiation.

Whether or not we support Cohnheim in his explanation of tumor etiology, we must grant that the more embryonal characteristics a tumor presents, the more malignant its nature and less hopeful the resultant prognosis. We must also acknowledge that all malignant neoplasms present in a greater or lesser degree certain embryonal characteristics.

However, the explanation of Cohnheim leaves without explanation several essential points and we are forced to reduce the problem to a far more basic consideration and study. For this purpose a detailed chemical study of the individual cell was made and this in turn reduced to its fundamental basis by

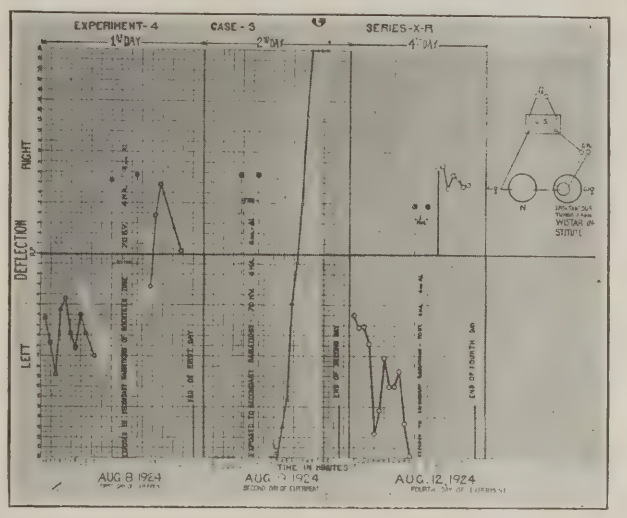

FIG. 7.—Chart illustrating the effect on cell potential under short, repeated exposures to secondary radiations from x ray tube.

a study of the physical or electrical composition and balance of the chemical atoms and molecules comprising the chemical elements involved in the structure of the unit cell.

I shall, at this point, hastily pass over the chemistry of the cell and merely formulate the fundamental facts determined, in order that the remaining portions of this report may be clearly understood.

First, let us consider the chemical composition of the spermatozoon. This structure consists of three distinct parts, namely, the head, neck and tail. The

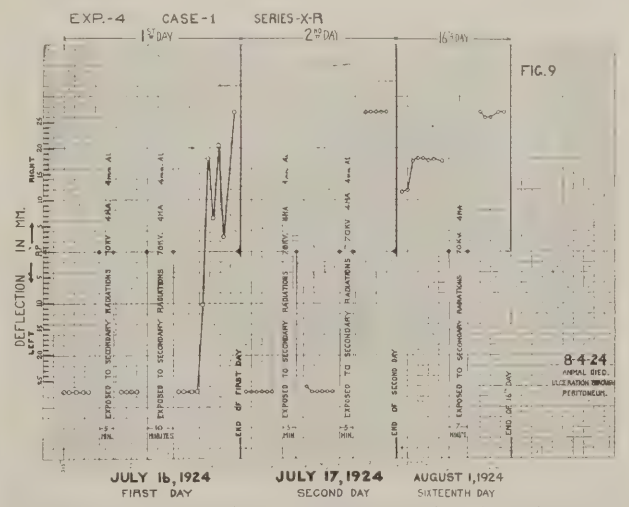

FIG. 9.—Chart illustrating the constant reduction of cellular potential brought about by beta radiation and the resultant "caustic" action of increased beta radiation.

two former alone enter into the process of cytology or spermatogenesis, the tail merely affording a means of propulsion.

For a basic analysis of the nuclear structure of all cells, the sperm head is most suitable, for these structures consist almost entirely of nuclear material, which, although very highly specialized, they are nevertheless nuclei.

After a series of suspendings, centrifugatings, and separatings, the heads are freed from the tails and offer pure nuclear matter for analysis.

The material so obtained is found to consist almost entirely of chromatin, which, upon examination, is found to be composed of two parts; one, an acid portion (nucleic acid); the other, a basic part (some member of the simple proteins). A more basic analysis of these two constituents of cell nuclei demonstrates that the nuclei acid is electronegative while the basic part (protamines or histones) are strongly electropositive, even in faintly alkaline solutions.

Regarding the other element necessary for cytogenesis, the ovum, it, like other unit cells, consists of a nucleus or germinal vesicle, surrounded by protoplasm. These components of the ovum are, as far as is known, of the same structure as those forming the structure, or electrochemic balance of other cells. This being the case we need not repeat the chemical and physical structure of the nucleus, but here merely mention several facts regarding the protoplasm.

The protoplasm consists of approximately seventy to ninety-three per cent. of water, hence the whole structure of this portion of the cell is of colloidal nature. All protoplasm contains an aqueous solution of common salts, and as we know, the outstanding property of salt solutions is their ability to conduct the electric current.

When the electric current is passed through protoplasm, accumulation of positive particles takes place at one point and of negative at another, the positive going to the cathode, while the negative accumulate around the anode. Since only electrically charged particles move with or against the current, the colloidal particles forming the protoplasm must be charged.

The points just formulated demonstrate that the protoplasm, like the nucleus, is composed of an electropositive and an electronegative portion, which, in the normal, resting cell is delicately and accurately balanced so as to carry out its portion of the cell's duty.

As shown in a preceding paragraph, the medium through which these positive and negative particles or portions interchange is well planned for electrochemical function of the cell, and the whole organism is a complete and powerful electrochemical unit. This reasoning cannot be denied, therefore why should we view with skepticism the idea that anything affecting this intracellular metabolism also being of electrical nature, or that the action of the agents used to combat altered intracellular mechanism must exert their influence by the physical or electrical structure and radiations.

Such physical agents not only exert their influence in the stimulated cell propagation demonstrated in malignant tumors but also upon the more rapidly multiplying cells which enter into the formation and development of the embryo. The work of past investigators has shown us that the growth of the embryo is retarded by radiation, and displays irregularities of development. Monstrosities have also been noted following irradiated embryos.

Now in order to simplify our problem, let us ask ourselves three questions which require answer before any rational explanation as to cause and treatment of cancer can be satisfied.

First: What is the alteration which takes place, causing a cell to undergo division? This I will attempt to demonstrate in a very brief manner by means of Fig. 2.

Second: What is the difference between normal cell division and that of the unrestricted cancer cell? This question has been quite thoroughly covered in several of my previous publications and need not be repeated at this time (1).

Third: A question previously referred to, but one which I believe cannot be too strongly emphasized, i. e., what is the sublethal effect of the various physical agents on normal and abnormal cell division? This will form the text for the balance of this report, and although the work is far from complete, I believe it has placed x ray and radium therapy upon a far more rational and fundamental basis.

SLIGHT DECREASE

Fig. 8.—Chart illustrating the lack of effect on cell potential by primary x radiation. The slight decrease in potential shown at the extreme right demonstrates the production of secondary radiations by passage of the primary beam through the body of the animal.

In answer to the first of the above questions, it has already been stated that all unit cells possess a nucleus and protoplasm, the former being electropositive as compared to the latter.

Now, with the fertilization of the egg by the spermatozoon, we might say that the bulk of the ovum is composed of electronegative material (protoplasm) although, like other cells, it possesses a positive element, the nucleus. When attacked by the spermatozoon, it is done so by a strong electropositive element, for, as previously outlined, the essential part of the spermatozoon entering the protoplasm of the ovum is the head, and composed of almost pure nuclear material.

Under these conditions we have the electrically balanced forces of the ovum (nucleus and protoplasm) stimulated to cytogenetic change by the addition of an electropositive agent. The nucleus of the ovum rapidly disappears and intermingles with the protoplasmic elements, and the whole structure at this stage exists in a strong electropositive state. Immediately following this initial stimulation, and transformation, the cell rapidly undergoes the various stages of division to form daughter cells.

It is quite natural that one should inquire into the nature of the force necessary for continuance of the process following the initial stimulus, and of the regulating force which enables this tremendous cell reproduction to be brought to a close, or at least modified and held in restraint.

The discussion of a question so involved as this cannot be presented in a condensed manner, so I will refrain from any such consideration in this report, however, this will be discussed fully in a later publication.

From the lengthy introduction to the experimental findings which form the body of this report, one is impressed with the idea that the cells comprising malignant tumors must exist in an electropositive state as compared to the normal, resting cell. *This I have found to be true by repeated animal experiments with many forms of experimental tumors, in vivo.* These experiments were subjected to the most strenuous forms of observation, and many factors were incorporated in order to offset the possibility of experimental error or misinterpretation of results obtained.

By means of a high sensitivity galvanometer, I have found, in some three hundred cases studied, that the tumor mass possessed a greater or higher potential than normal tissue.

Analysis of the radiations emitted from the element radium, shows the presence of three rays, two of which are definitely charged particles:

1. The alpha particles, or positively charged helium atoms. These have a wave length of about five cm. (the greatest range being 8.6 cm., which is that of the alpha particles from thorium C_2). These particles are readily absorbed, the thinnest walls of any container for radium application will easily eliminate their passage. Therefore we may disregard such particles as having any therapeutic value.

Allow me at this point to say that a series of experiments has been started whereby it is my hope to induce tumor formation by the action of the alpha particles emitted from polonium, or radium F.

This work offers encouraging results, as sections taken from areas immediately surrounding the polonium needles demonstrates structural abnormalities resembling those of the early stages of cells undergoing malignant transformation. However there are two important factors entering into this investigation which will make it one of considerable length before definite results can be reported. This experiment was carefully controlled by placing victrola needles, under the same experimental conditions as the polonium needles, into normal control animals.

The factors requiring consideration are:

First: That the penetrability of the alpha particles being so small, comparatively few are able to penetrate the protoplasm of the cell and react upon the nucleus. Only those immediately surrounding the polonium surface would be within range of the emitted particles.

Second: That the period of activity of the polonium being of such short duration (half decay period being about 136 days) only the cells immediately surrounding the surface of the needle would be stimulated by the emitted alpha particles, and sufficient time of exposure would have to elapse before such cells could adopt the metabolism and habit chemistry of the electrochemical typical cancer cell. It must also be remembered that during this and subsequent times, there is a comparatively rapid loss of activity or alpha ray output.

Our problem is now reduced to the study of the remaining emissions from the element radium, i. e., the beta particles, and the gamma rays.

The beta particles consist of negatively charged particles, or negative electrons, having a penetrating power of about one hundred times that of the alpha particles. The beta rays, upon their passage through matter give rise to a type of gamma radiation, which in turn, upon further passage through the medium give rise to secondary beta rays, or negative electrons.

The gamma rays are electromagnetic waves with a velocity equivalent to that of light. These rays are not deflected by a magnet and have a penetrating power ten to one hundred times that of the beta particles. As the gamma rays pass through matter a part of the original beam is scattered in all directions, giving rise to secondary gamma rays and secondary rays of the beta ray type. These secondary beta rays have a penetrating power nearly equivalent to the primary beta rays. It seems quite possible were the thickness of traversed tissue sufficiently great, that the secondary gamma rays formed by the splitting of the primary beam, would eventually give rise to tertiary beta rays, with greatly decreased power of penetration.

These three forms of radiation from radium find their parallel in radiations from the röntgen tube, differing only in mode of origin, and to some extent in penetrability. However, that does not alter the fact that electrically, these radiations, from two distinct sources, are identical. Thus in the scattering of rays and radiations from either radium or the röntgen tube, the end product is the formation of negative electrons, and it is upon this fact that this research is based (Figs. 3 and 4).

In a recent publication, the results of an extensive research of the biophysical effects of the rays and radiations from radium were fully discussed (2). The important points advanced in this report were as follows:

First.—That the beta particles, or negative electrons, are the ones responsible for biological cell change, and these, by neutralizing the excess potential within the tumor cells, bring about their desired and selfpossessed therapeutic action, by repeated small doses of screened radium, or radium emanation, rather than the large and continuous doses heretofore employed (Fig. 5).

Second.—That a continued negative state of physical unbalance within the cell will result in inhibition of cellular activities, and an eventual cell death.

Third.—That the biological action of gamma

radiation is practically nil, and the noteworthy feature in the treatment of malignant neoplasms is their penetrability and vehicle or excitant for secondary beta rays, or negative electrons. This was demonstrated most conclusively by experiment (Fig. 6—A and B).

Fourth.—In all probability, the burning, ulceration and constitutional reactions developing as the result of long, continued and intense radiation is the result of the continued physical action of the primary or secondary beta rays, or negative electrons (compare with 2). This has been proved by our experimental and clinical findings.

Fifth.—The nausea, vomiting, depression, and other symptoms following large doses of radium is due, to a great extent, to the absorption of the products of cell death by the entire organism.

As stated in a previous paragraph, such radiations as emitted from the radioactive element radium have their analogies in radiations from the röntgen tube:

1. The canal rays consist, under certain conditions, of positively charged helium atoms, which are low velocity alpha particles.

2. The particles of the cathode stream are low velocity electrons, i. e., slow beta particles, or negative electrons.

3. The x rays are, as far as is known, identical with the gamma rays.

Now in order to further substantiate our experimental findings of the biological action of the beta rays, or negative electrons from radium or radium emanation (niton), and in an effort to bring to light a more detailed knowledge of the basic action of radiations from the röntgen tube in the treatment of malignant processes, an extensive physical and clinical study of the secondary radiations from the röntgen tube was undertaken. The theoretical aspect of this investigation was covered in an earlier publication (3).

This investigation has yielded extremely interesting findings and we now believe that with a more detailed study of the secondary radiations, or negative electrons, together with a more perfected technic, that the ravaging processes of malignancy may be held in check, and succumb to the power of this physical agent.

We are now directing our efforts toward a technic whereby the primary beam is scattered, giving rise to its secondary rays and radiations. Knowing that the secondary cathode particles so formed are electrically charged particles, or negative electrons, we hope to be able to make use of this property and direct or attract such particles to the desired locality by means of proper magnetic forces.

By animal experimentation we have found that the secondary rays alone produce any initial effect upon the increased potential demonstrated by tumor masses (Fig. 7). This was previously found to be a property of the beta rays from radium (Fig. 5).

Corroborating the findings of the lack of effect of gamma rays from radium upon increased potential of tumor cells, we have found that the primary beam of x rays bring about no alteration of potential in such structures except after they have penetrated sufficient material to give rise to their secondary radiations (Fig. 8).

Verifying the theory and subsequent experimental findings, that a continued negative state of cellular reactivity will eventually result in ulceration and sloughing, we have found that neoplastic tissue, once treated with an antidotal dose of secondary radiation, will, upon further treatment, display a reversed reaction, and if maintained in this state of physical unbalance, will readily ulcerate, with an eventual outcome of death to the animal so treated (Fig. 9).

Animals treated with a sufficient dose of secondary radiation to bring about a balanced potential of neoplastic and normal, demonstrated marked beneficial local and constitutional results.

As the clinical results following such treatment as suggested in this report will be covered in a detailed manner in a paper by my associate, J. W. Frank, M.D., I will refrain from infringing upon his report, but here merely mention that physical alteration of the cell balance was brought about only by the negative electron.

The way in which the electron exerts its influence within the cell can only be answered by hypothesis, and in concluding this report I will attempt to outline very briefly a possible explanation of its behavior within the body cell.

As far back as 600 B.C., the phenomenon of electrostatic attraction was observed. In 100 A.D., Plutarch recorded that a piece of lodestone sometimes attracted and sometimes repelled iron. Observations from these dates on have brought about the establishment of the law, "unlike poles attract" and "like poles repel."

In our present century, Bohr (4), in describing the structure of the hydrogen atom, states, "we could indeed hardly conceive of a system composed of four positive hydrogen nuclei alone, for the forces of repulsion would soon drive the separate parts asunder. The two electrons can, so to speak, serve to hold the system together."

Applying the laws of attraction and repulsion to the electrical structure of the cell as outlined in this report, we may view the entire problem as based on such fundamental principles.

With increasing potential of the cell there naturally results an accumulation of positive elements. The cell, like the atom, requires a definite balance of protons (positive elements) and electrons (negative elements), some electrons associated with the positive elements of the nucleus but the bulk surrounding it.

Drawing such a comparison, we could no more expect the cell to be held together, when once this balance of protons and electrons is disturbed, than we could the atom. Therefore, with an increasing positive state of the nucleus, the nuclear elements are repelled, and the cell undergoes division. This may account for the usual rapid progress of sarcoma as compared with carcinoma, for cells supported by the structures which are usually the site of sarcomata, requires a greater physical or electrical alteration before the necessary stimulation could be brought about. The alteration once produced, the cells propagate and proliferate at an astonishing rate.

If the negative electron is the one responsible for correction of such malignant processes, and from theoretical reasoning and actual experimental findings this is found to be true, it is our goal to place into the cell only enough electrons to balance the in-

crease of positive elements, thereby holding the system together.

In cases demonstrating the caustic action of radium and the x rays, I believe that with excessive doses we are so saturating the cells with negative electrons that the forces of repulsion drive the separate parts of the cytoplasm asunder; the nucleus, then positive, and existing by itself, is not held together by the negative forces of the cytoplasm and therefore disintegrates. Or perhaps the planetary electrons from an atom of radium so saturate the entire cell as to cause complete disorganization of the cell components.

The mode of action, or mechanism, of the electron within the body structures (or within the individual cells, if possible) will form an extensive and important part of our remaining research; and it is our hope and desire to be able to acquire a more basic knowledge of this physical agent, for it is only through such a knowledge that x ray and radium therapy will be put upon the sound foundation so imperative in our fight against cancer.

Experimental and Clinical Evidence Supporting the Action of the Secondary Radiations from the Röntgen Tube in the Treatment of Malignant Processes

J. W. FRANK, M.D.
Philadelphia

In the early years of the x ray era many difficulties were encountered; this was apparent to all clinicians but especially so to those in direct contact with the work. These difficulties for the purpose of study may be divided into two main groups: First, inadequate apparatus, and second, lack of a scientific basis as a guide for therapeutic application of the rays.

The first stumbling block has been ably handled by the commercial part of the profession. (I classify these men as part of the profession because they have been instrumental in advancing the science in no small degree.)

The early work was of necessity done with crude instruments such as static machines and coils as a primary source of power. Gas tubes with their ever changing degrees of vacuum, resulting in mixed wave lengths and varying degrees of penetration, thus making it almost impossible to determine the exact amount of radiation reaching the involved pathology. This has happily been overcome by the intervention of the hot cathode tube by Coolidge in 1912 and the improved generating plants giving outputs as high as 300,000 volts thereby placing in our hands apparatus capable of developing extremely high penetrating rays, always under the control of the operator.

Second—In spite of the enormous amount of work done and the results accomplished there was nothing that we could recognize as a definite law of therapeutics; the reason for this is indeed obvious, there being no basic knowledge as to the nature of cancer, therefore not knowing its fundamental abnormalities no definite technic could be evolved.

The reported researches of Butts (1) have thrown considerable light on the biophysical and chemical nature of cancer and now we feel we are on the verge of formulating a scientific rule of therapeutic application which will result in relief if not the ultimate cure of the cancer victim.

In our experimentations we found that the secondary rays were the most beneficial, and that the overwhelming excess of negative electrons produced by the splitting of the primary beam was the ultimate cause of the intense sloughing following prolonged treatments, so that at present we make use of the secondary rays in all of our work, the results of which are offered in a more or less preliminary manner in this report.

The aim of radiologists in the past has been to apply as much radiation to the cancerous growth as possible; this was limited by the effect on the skin. Filters were then introduced, being interposed between the tube and the patient, their function being to filter out the low penetrating rays that would act only on the skin, and not the deeper tissues, thereby allowing more of the deeper penetrating rays to reach the mass. Then followed the cross fire method, this to increase the total amount of radiation to reach the cancer, always figuring that it was necessary to apply 110 to 120 per cent. of a skin dose to the growth; this was considered the lethal dose for carcinoma and it was believed this was the ultimate goal to be reached. We now know it is not necessary to give a dose sufficient to kill the neoplastic cell.

From our experiments it has been demonstrated that it is not the caustic action of the rays that is beneficial but the action of the negative electron, conveyed by the secondary rays, which will bring about a balanced electrical condition of the cell, thereby controlling cell energy and metabolism and by this means arresting the cancerous proliferation.

As to the best method of producing and applying the secondary rays much work needs to be done in order to perfect a technic bearing out the application of such radiations, but directed to meet the requirements of the individual case. Two methods employed in my laboratory are formulated as follows:

Method I: 70 K.V., 4 ma., 12″ distance, 4 mm. aluminum and 3.2 c.m. of paraffine 12-20 min.

Method II: 70 K.V., 4 ma., 4 mm. aluminum, 12″ distance for 12-20 min. and pass the beam through 12-14 cm. of paraffine, one edge of which is about 1 c.m. from the primary beam, this giving

Fig. 1

Fig. 2

Fig. 1.—Photograph of rat bearing Flexner rat carcinoma, taken July 18, 1924. Size of tumor on this date, 5.2 c.m. by 2.6 c.m. Animal thin and anemic.

Fig. 2.—Photograph taken July 23, 1924 of same rat as illustrated in Fig. 1. Animal has received twenty-five minutes of secondary radiation. Size of tumor on this date, 2.5 c.m. by 1.5 c.m. General condition markedly improved.

off principally secondary rays, the primary beam not touching the patient; this latter method we feel is the best way to reach the cell to change it to one of neutral reaction and has been employed almost exclusively throughout the animal experiments.

In the deep seated growths our efforts are directed in such manner that the secondary rays are produced in the tissues immediately surrounding and within the mass. All the experiments have been accurately checked in the following manner:

Each case was photographed and röntgenographed, after which a section was taken for microscopical examination, the animal was then coupled with a normal control and reactions tested by means of the high sensitivity galvanometer to determine the potential difference demonstrated by the neoplastic and normal tissue prior to and following secondary radiations.

It was found that doses as described under the second method reversed the current flow displayed at the onset of the experiments. If such alteration was not brought about as a result of such exposure the animal was either subjected to further treatment at this time or the experiment discontinued until the following day, whereupon we found that very short exposures produced rapid reversion in current flow, demonstrating that the tumor mass formerly with a greater potential now displayed the effect and physical action of the electron.

With the maintenance of a decreased potential, or in other words a balanced equilibrium, or ionization, marked atrophy of the tumor mass resulted; however, with a continued negative state of the mass so treated, extensive sloughing and ulceration, followed by the death of the animal resulted. Animals treated with a neutralizing or antidotal exposure of secondary radiation showed rapid constitutional as well as local effects, the anemia and cachexia rapidly disappearing, accompanied by an increase in body weight and associated with all the activities and vigor of the normal controls.

The investigations of Butts (4) demonstrate that all carcinomatous masses deflect the galvanometer to the positive side thereby showing a higher electrical potential in contrast to the normal body cells which are endowed with a well balanced or neutral reaction. This being true it primarily remains for us to apply a force that will reduce the excess potential to the neutral reaction of the normal cell; this force we have found to exist in secondary radiations.

The use of these rays in our animal experimentation brought about such noticeable and beneficial changes in the carcinomatous masses (as shown by Figs. 1, 2, 3, 4) that we have been applying them clinically to the exclusion of the primary beam wherever possible, results of which we hope to be able to report on more fully in the near future.

A research as extensive as this requires the maintenance and employment of many animals, born and bred under the most careful experimental conditions. Rats must be inoculated with the standard strains of laboratory tumors, and besides these, control rats of the same age, strain and litter are necessary.

In an effort to control our experiments with the greatest degree of accuracy we have constructed cages of sufficient size to accommodate two animals. In each cage two brothers or two sisters of the same litter are placed.

These cages are built so that the animals are maintained under identical conditions of living and diet, and assuring ample room for exercise and the most pleasant environmental conditions.

The tumors now established in my laboratory are the Flexner rat carcinoma and rat sarcoma No. 10, besides various types of spontaneous tumors (Figs. 5, 6, 7, 8) received through the kindness of the Wistar Institute of Anatomy and Biology. This selection of tumors afford ample material for a thorough study of our problem, for it is absolutely essential that any theory as to cause and treatment of cancer must also cover all types of tumor formation.

All rats used throughout this investigation are from the Wistar Institute colony and in using animals from such a source we are assured of exact date of birth, and of the animals being free from any previous pathological condition or the presence of external parasites.

Fig. 5.—Lipoma.

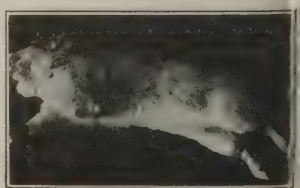

Fig. 7.—Adenoma.

The tumors are transplanted from one animal to another by the method devised by Butts (5) which usually assures a high percentage of successful grafts without loss of tumor bearing anmials or identity of the tumor type. In about two or three weeks the tumors have developed, if the graft has proved successful, and from this time on offer suitable material for our work, depending upon the stage of tumor development required.

Following out the leads as shown by our experimental work previously mentioned we are now applying them clinically, and have under treatment a number of cases which are showing marked improve-

ment, some of which under the older technic did not respond, in fact many became worse from the excessive exhibition of negative electrons.

CONCLUSIONS

1. That the older form of treatment with the filtered primary beam would sometimes result in relieving the patient and prolonging life, others treated would not be benefited. The results obtained by such forms of treatment we believe entirely dependent upon the natural liberation of secondary rays created by the passage of the primary beam. In this method of therapy benefit or failure depended upon three factors enumerated as follows: First, that in some cases so treated the primary beam passes through the involved pathology without liberating sufficient secondary radiations to be of any actual benefit. In such cases there would naturally be little, if any cellular response to radiation. Secondly, the primary beam in its passage through the treated area liberated sufficient electrons to bring about marked alteration (antidotal dose), and benefit in the pathology so treated. It was such exposures as these that held out hope for the x ray in the treatment of malignancy. Thirdly, that the ulceration and sloughing so often experienced was due to the liberation of a greater excess of electrons than was demanded for the beneficial action of x ray therapy.

FIG. 8.—Radiograph of animal illustrated in Fig. 7, showing extent of adenoma.

2. That this was due to excessive radiation with primary negative electrons.

3. That the physical nature of cancer is shown by the increased potential of its cells.

4. That this increased potential can readily be changed to a normal balance by applying neutralizing or antidotal doses of secondary radiations.

5. When secondary radiations were so applied, all animals showed an almost immediate local and constitutional benefit.

6. That the benefit noted in the animals will also be manifested in humans, as already shown by a number of clinical cases under treatment and close observation.

A table[1] has been prepared consisting of a composite of twenty-seven cases now under treatment with an increased secondary ray production from the röntgen tube. A number of these cases were inoperable and advanced beyond the stage where radium therapy was advisable. Many of the cases reported in this table had completely failed to respond to the old form of x ray therapy. Twenty-one of the twenty-seven patients have demonstrated marked local and general improvement, responding almost immediately to the treatment with increased secondary radiations, and all have shown improvement to a noticeable degree.

[1]This table with a complete list of references will appear in the author's reprints.

A Case of Lateral Sinus Thrombophlebitis

Recovery Without Operation

ADOLPH WEIZENHOFFER, M.D.
New York

That thrombophlebitis of the lateral sinus is almost invariably fatal, when unoperated, is admitted by everybody. Yet there are a number of cases, larger perhaps than we are inclined to think, in which a spontaneous cure takes place. This may be brought about in one of two ways:

1. The ends of the sinus are shut off by a thrombus, while the outer wall of the intervening portion breaks down and the pus is discharged into the mastoid, drainage taking place either through the middle ear, through a mastoid operative wound or through a fistula in the mastoid wall. Friedenwald reports a case in which the pus was evacuated through the emissary vein, which served as the fistulous tract, while the sinus was shut off from the circulation by firm clots.

2. The thrombus in the sinus may become organized. In this group the infection is usually of a low grade permitting organization. Ewing W. Day reports six cases of sinus thrombosis with mild symptoms which were unsuspected, but were found during mastoid operation. In these cases the sinus was filled with an organized clot. Rarely even malignant cases may show organization and sometimes even recanalization. Haymann reports a case of otitic meningitis in which autopsy revealed the sinus obliterated by organized connective tissue, showing undoubted evidence of recanalization.

In the cases reported in the literature the diagnosis was established either at autopsy or accidentally while doing a mastoidectomy. Friedenwald reports another case in which the outer wall of the sinus was found destroyed and the lower end collapsed. He also collects the following cases from the literature:

Griesinger, Schwartz, Alt, Politzer, Baufal and others found complete obliteration of the sinus at autopsy. Alexander, Ucherman, Blau, Uffenorde, Streit, Welty, Auerbach and others report cases which ran a nonfebrile course and in which the sinus was found obliterated at operation.

In the case here reported we have not been so fortunate, as the mastoid operation was done before the onset of symptoms pointing to sinus involvement. Even the blood culture was persistently negative. In this case also the symptoms were unusually severe, the patient seemed to be suffering from a very severe pyemic infection, lasting a long time, and her chances for recovery seemed doubtful.

CASE.—B. M., female, aged thirty-five, was admitted to Dr. Hubby's service at the Harlem Hospital on February 14, 1922, giving the following history: Ten days before admission patient had rightsided earache. Two days later the drum was incised by a private physician. On account of failure to discharge and beginning mastoid pain the drum was again incised six days later. This was followed by a profuse purulent discharge.

On admission, examination revealed the following: The left ear was normal. The right concha was red and swollen (the patient thought this was due to a hot water bag burn). There was a profuse purulent discharge from the right ear, the drum looked red and boggy and the posterosuperior wall was perceptibly sagging. There was marked tenderness over the mastoid region especially severe over the tip. The temperature was 101.2°.

By evening the temperature had risen to 104.8° and the differential count showed white blood cells 12,000, polymorphonuclears eighty-four per cent., lymphocytes sixteen per cent. Operation was decided on and a simple mastoidectomy was done the same evening. While elevating the periosteum, the mastoid emissary vein was injured causing rather profuse bleeding, which was soon controlled. The mastoid tip was necrotic and full of pus. The bony wall of the sinus was not injured and left intact.

After operation the temperature rose still higher and remained steadily high for four days between 102.5° and 105.5°. The blood count showed white blood cells 9,000, polymorphonuclears eighty-two per cent., lymphocytes eighteen per cent. The patient complained of headache. About this time the skin in front and behind the ear became red and swollen and erysipelas was suspected; but this diagnosis was not positively established until the seventh day, by which time the infection had spread over the scalp to the left ear. This put our fear of thrombosis at rest temporarily.

On the fifth day the temperature dropped suddenly from 104° to 97.4°, and thereafter fluctuated widely between normal and 107° with chills and sweats. On the thirteenth day the erysipelas had reached the left cheek, when all advance ceased coincident with a gradual fading of the redness. At this time also the patient complained of severe pain and tenderness in the right gluteal region. The differential count was white blood cells 8,600, polymorphonuclears seventy-eight per cent., lymphocytes twenty-two per cent.

The persistence of the fluctuating temperature, the severe chills, the profuse sweats, the possibility of secondary abscess in the gluteal region and the cessation of the erysipelas turned our suspicions to the sinus once more. A second and third blood culture taken on the thirteenth and sixteenth days respectively were negative.

About the beginning of the third week after operation the patient complained of pain about the mastoid wound. The region about the emissary vein became edematous and one could feel a tender cord running from the mastoid along the border of the sternomastoid muscle. The blood count was white blood cells 12,600, polymorphonuclears, eighty-seven per cent., lymphocytes thirteen per cent. It might be stated here that repeated careful examinations revealed no other cause for the temperature.

The fact that the patient did not seem extremely septic during the whole course of her illness, that her general condition was always fairly good and that the gluteal pain was subsiding, made us decide against operating, great as was our temptation to do so. To our great surprise and satisfaction the temperature dropped to normal on the twenty-first day and remained there, the patient being able to leave the hospital four weeks after operation.

In arriving at a diagnosis the complicating erysipelas proved to be a stumbling block for a time. However, the fact that all signs of advance of the erysipelas had ceased after the thirteenth day, while the septic temperature persisted until the twenty-first day, and also that the temperature in erysipelas is not of this widely fluctuating type, soon ruled out this affection as one of diagnostic significance.

Although we made the diagnosis of thrombophlebitis with some hesitancy, we feel that all the signs and symptoms that we were able to obtain pointed to such a cause. If we were asked why we did not operate, we would have to admit that we do not know, except that circumstances made us hesitate at first, and the longer we waited the less inclined we were to interfere.

The Occluded Fallopian Tube and Its Relation to Cervical Infection*

IRVING SMILEY, M.D.

New York

Female sterility, notwithstanding advances made in recent years, continues to present many baffling problems to the gynecologist. Much has been done in almost every branch of medicine to aid in the solving of this condition which often assumes so many mysterious aspects. Volumes have been written about sterility but we stand today practically helpless in the majority of cases. Notwithstanding the abortive results obtained in the therapeutic field much has been accomplished in the diagnosis and prognosis of sterility. The problem here is in every respect one of cause and effect. Find the cause and the problem is usually solved.

Among the many notable advances in the past few years, the insufflation test for the determination of the patency of the fallopian tubes undoubtedly ranks highest. It has revealed the fallopian tubes in their true light, as a distinct clinical, pathological entity, and has helped demonstrate, with comparative ease and safety, conditions that formerly required laparotomies for their recognition. It has enabled us to ascertain with assurance, the possibility or improbability of relieving a common condition. The Rubin test, other conditions being favorable, should be used in every case of sterility before relief for its correction is attempted, especially before any abdominal surgical procedure is advised.

Omitting in this short paper all those cases of sterility that have as their basic cause some definite gross anatomical deformity or gross pathological abnormality, such as congenital defects, new growths, pelvic displacements, inflammatory masses in the adnexæ, and other constitutional factors, our theme here concerns itself with those sterile women in whom bimanual examination fails to reveal any of these conditions. The histories given by these patients are almost identical in their character. A slight discharge before marriage, somewhat more profuse after sexual relations have been established, perhaps dysmenorrhea in some cases, and sterility. Examination reveals uteri freely movable, adnexæ apparently not the seat of inflammations or inflammatory exudates, the Rubin test, however, disclosing nonpatent tubes. In many thousands of such cases tested, it has been definitely established that approximately between forty per cent. and forty-five per cent. of the patients have tubal obstruction.

Where abnormalities or deformities are present and can be diagnosed, the problem of their correction assumes a much simpler aspect, and the possibility of a cure by the employment of the proper corrective measures suitable to such deformities should be tried, and a reasonable assurance of success expected. This is particularly true of patients in whom conditions in the fundus uteri are the predominating etiological factors. Where gross pathological conditions in the adnexæ are diagnosed, the possibility of relieving sterility is rather remote, although many cases are at hand in which conservative treatment was followed by conception. This may often take place in undoubted cases of gonorrheal pyosalpinx. Such instances are rare, however, and it can be stated that, as a rule, tubal occlusion invariably follows severe adnexal disease. This occlusion often accounts for the alternate filling and emptying so frequently observed in pyosalpinx, hydrosalpinx, and other conditions. It may be stated in passing that conservative treatment in this group should be the method of choice, and, when feasible, the etiological factors sought for and eradicated.

A more difficult problem revolves about that group in which physical examination reveals no abnormality in the fundus or in the adnexæ. The Rubin test, however, discloses the tubes to be nonpatent. Shall we inform such patients that the condition as found is a relatively hopeless one, or shall we advise surgical measures to overcome the obstruction and render the tubes patent? And, if surgery, what measures shall be pursued to afford at least a reasonable hope of success? Within the past several years, salpingostomy and various other plastic operative measures on the fallopian tubes have been advised, and assertions have been made that from twenty per cent. to fifty per cent. of such surgical measures were successful, and conception occurred in due course of time. Such statements bring to mind the phenome-

*Read before the Bronx Gynecological and Obstetrical Society, March, 1924.

nal cures formerly attributed to dilatation and curettage, the use of the stem pessary and the various other panaceas broadcast far and wide as cures for sterility, only to pass into oblivion, and it seems that we are about to traverse the same path, employing at this time a vehicle more complicated, more intricate and much more dangerous.

Many causes operate to defeat successful surgical plastic work on such fallopian tubes. Among them may be mentioned the manipulations of the tube incident to this type of work, with the subsequent postoperative adhesions, the attempt at loosening old adhesions leading only to the formation of firmer and denser bands, the frequency of reinfection from below, and the tendency on the part of nature, nearly always constant, to seal up the tubal stump with a plastic exudate soon after the closure of the abdomen. Individually each is of sufficient importance to bring about failure in so delicate an operation. Finally defeat is inevitable snce such attempts at correction omit and ignore the basic etiological factors concerned in the production of such tubal obstructions. These surgical measures are both unscientific and unsurgical, since little cognizance is taken of the fact that occlusion of the tube is seldom, if ever, primary, and is nearly always the result of a preexisting infection from the lower genital tract, which in itself is often sufficient to cause sterility. The recognition of this fact and the full knowledge of its significance would materially lessen the incidence of such operations.

Omitting from this group the small number of cases of tuberculous adnexitis, and those in which tubal occlusion can be definitely shown to be the result of a previous suppurative appendicitis, it can be stated that in the main these tubal obstructions are brought about and are the result of infections from below. This holds true in both primary and relative sterility. The pathological picture present in cases of relative sterility is simple to understand, and the infections incident to the traumatisms of childbirth are quite familiar. Much the same can be said for these insidious infections, that ultimately follow dilatation and curettage. The primary sterile women with little or no history to guide one, presents an almost similar pathology as far as the infection is concerned, perhaps not so marked, but with corresponding end results. In both classes the obstruction is definitely due to an infection.

The microorganisms usually responsible for this infection are the gonococcus, the staphylococcus and the streptococcus. They easily find their way into the genital tract and here meet favorable media for their propagation. This is as true in early childhood as it is in adult life, and the vulvovaginitis of children is rather a cervicitis than a vaginitis. In later life the incidence of infection is more frequent, and cervical infections are the commonest of all lesions found in the entire realm of gynecological pathology. Anatomically and histologically the cervical canal is ideally adapted to receive and maintain these germs. They find their way into the ducts of the racemose glands that honeycomb the cervix, and penetrate deep into the glandular tissue itself, remaining here for years or even a lifetime. The acute stage of the infection is readily tolerated by the patient as a rule, and may last only a short time. It progresses however insidiously, soon assumes the chronic form, and presents the clinical picture of chronic endocervicitis. Various pathological pictures may be seen, ranging from the case that shows little or no cellular destruction of the vaginal mucous membrane, and where the infection is confined wholly within the cervical canal, to the marked destructive processes that manifest themselves in the socalled erosions and ulcers. Although these changes depend upon the degree of virulence present, the end results, to all intents and purposes, are similar.

Leucorrheal discharge is present in all cases, and the history of such a discharge is sufficient in itself to make a diagnosis of endocervicitis. This discharge is an attempt on the part of nature to throw off the products of inflammation, but unfortunately the drainage is nearly always inadequate and little is accomplished. The normal character of the cervical discharge is altered, becoming thick, inspissated, sticky, and its chemical reaction changed. Examination of the secretion taken from the cervix after coitus without condom, often shows that not only are the spermatozoa frequently killed when the reaction is acid, but will disclose them entangled and enmeshed in this inspissated discharge, unable to make headway through this mass of pus and mucous. It is, therefore, not unreasonable to say that a progressive endocervicitis is frequently the first and only link in the chain of circumstances that ends in sterility, and that this condition is well established long before involvement of the tubes has taken place. The futility of abdominal surgery in this type is at once apparent, it may be said here as a corollary that it is advisable to precede the insufflation test in many cases by Hühner's test.

With the gonococcus as the dominating etiological factor in the production of the cervical infection, the tubes become involved through their migration along the uterine cavity and thence to the tubes. Depending upon the virulence of the infection, the degree of tubal involvement will vary from a simple catarrhal salpingitis to a severe pyosalpinx. As a rule the infection is mild and an endosalpingitis results. Tubal obstruction takes place from the agglutination of the opposing mucous membrane surfaces. The walls of the fallopian tubes are soon invaded, fine adhesions are thrown around the tubes, which bend, twist and kink them into various shapes and forms. These factors alone are sufficient to cause obstruction. In the main, the occlusion takes place at the fimbriæ and is brought about by the folding back of the fimbriæ on themselves back into the orifices of the tubes, thus becoming agglutinated through opposition of their various surfaces. An infundibulitis takes place, which destroys the mucosa on both surfaces of the fimbriæ, thus rendering possible their fusion and retraction, and under the influence of an atrophic influence the infundibulum is transformed into a cicatricial stump which is capped by adhesions.

With tubal deformity similar in character as far as the end results are concerned, the clinicopathological reactions engendered by streptococcal and staphylococcal infections vary from the above in several ways. With this type of infection, the lymphatics play an important rôle in its dissemination. The uterine lymph current can be traced from its

lacunar origin into the cervical and corporeal mucosa through minute funnel shapped ostia directly to the myometria. Here it branches into an extensive capillary net, and drains into two main collecting channels that course parallel to the uterine and ovarian bloodvessels at the base and top of the broad ligaments. The tubal musculature is likewise honeycombed with these lymphatics, and the infection from the cervix invading these lymph channels causes an ascending lymphangitis. The reaction is more pronounced in the tube, due not only to the thinness of its walls, but also to the fact that here the terminal lymph channels are located. The serous coat is soon invaded in the process, and a perisalpingoperitonitis, more commonly known as perisalpingitis, takes place. This is characterized by the formation of dense, firm bands of connective tissue that gradually distort the tube often out of all recognition. This alone is often sufficient to cause obstruction.

With the more virulent types of infection, small miliary abscesses may form in the terminating lymphatics of the tube, which rupture into its lumen with subsequent involvement of the endosalpinx. Usually the pathological picture present is that the fimbriæ are more or less preserved but are enveloped in a fibrous pocket without being involuted. Here the walls are formed by the organization of inflammatory exudates. The process of obliteration is simply due to an exudative periinfundibular peritonitis which becomes progressively organized. With a pathological picture present such as this, even when the cervical infection will permit the entrance of living spermatozoa into the fundus, it is reasonable to assume that no plastic operative measures upon such tubes should be undertaken until the etiological factors have been eliminated. As sterility plus tubal obstruction are only sequelæ, treatment should first be directed against the original disease, before any attempt is made to correct the resulting deformities.

It is unreasonable to assume that obstruction can be relieved and patency maintained by any form of surgery when the focus of infection remains with its known power of repeated reinfections both present and active. Under such conditions, surgical means to restore nonpatent lumens can only be temporary, leading to more severe closure, this in spite of postoperative insufflation.

Occasionally, a salpingostomy will be followed by a successful result. This occasional success can be accounted for by the fact that in some instances, the cervix after a time is able to rid itself of all microorganisms, leaving behind a hyperplasia of the mucous membrane. Examination in such cases reveals a slightly enlarged cervix, a thick mucoid discharge, but no bacteria present, in repeated smears or cultures. In such a cervix the power of reinfecting the tube is eliminated and an attempt at radical treatment may be tried. Such instances are, however, the exceptions.

Upon premises such as have been outlined above, the treatment of tubal obstruction should begin with a thorough survey of all the etiological factors concerned in its production. Where gross anatomical deformities are present, especially those relating to the fundus uteri, the point of attack should be in this direction. In the presence of adnexal inflammatory masses, conservative treatment should be the method employed, and a thorough removal of any etiological factor instituted at the proper time. Where examination fails to reveal fundal or adnexal conditions, possibly only a slight thickening, palpable in one or both fornices, the cervix will usually be found to be the seat of the infection, and early and thorough treatment is indicated to avoid the development of local barriers to the ingress of spermatozoa and to prevent the further internal extension of the infection. A careful study of the cervix should be made in all cases, and Hühner's test employed to determine the effect of the secretions upon the sperm. The prophylaxis of tubal obstruction will find its greatest usefulness in the early recognition and correction of cervical infection.

TREATMENT

It therefore becomes a matter of much importance as to what the proper and appropriate treatment should be. Local medicinal treatment of cervical infections, except in the mildest forms, is practically useless, since no local medicinal agent could possibly reach the deeper glandular structure. The application of radium in small doses may succeed in removing the diseased mucous membrane in a certain percentage of cases and can be tried. The method of choice however and the only one that will render the greatest number of successes is the surgical removal of the diseased mucous membrane. The ideal operation is the one that will remove the entire infected area without disturbing the anatomical and physiological relations of the parts involved. It should demand a complete enucleation of the entire infected endocervical mucosa, the preservation of its muscular structure, and the accurate relining of its denuded canal by an ample cylindrical flap from its vaginal sheath to obviate cicatricial contraction of its canal. An experience of many years with this form of tracheoplastic procedure, more than ever convinces me that it is ideal in accomplishing the desired result. With the removal of the infected area and the relining of the cervical canal with healthy vaginal mucosa, the danger of reinfection of both the cervix as well as of the tube is eliminaed. The lymphangitis gradually disappears, and the powerful regenerative faculties of the female genitalia manifest themselves in many cases by restoring such tubes back to normalcy.

A course of proper physiotherapeutic measures will aid very materially in the loosening of the old adhesions. Repeated insufflations should be employed as soon after operation as is consistent with safety, and at least one year allowed to pass before any further attempts at radical treatment be instituted.

SUMMARY

Summing up the subject, I would say that tubal obstruction is rarely a primary condition; that it is the result of an infection; that the focus of infection can be found in the cervix in the majority of cases; that this infection is chronic in character and consistently reinfects the tubes, and that proper treatment should demand the early and proper removal of this infectious area prior to any surgical attempt upon such obstructed fallopian tubes.

1018 East 163rd Street.

Practical Therapeutics

THE BASIS AND DEVELOPMENT OF A SYSTEMATIC RESPIRATORY THERAPY

LUDWIG HOFBAUER, M.D.
Vienna, Austria

The subject of the useful and the injurious effects of the individual parts of the respiratory act (inspiration, expiration, etc.), and their etiological significance in the occurrence of pathological changes were investigated. A systematic investigation of the thoracic organs of healthy and diseased persons was made possible with the aid of röntgen rays. This brought forth an entire series of new facts regarding the participation of the internal portions of the thoracic wall (diaphragm and mediastinum) in the act of respiration and made the direct visualization of the effect of the normal and pathologically changed respiratory act upon the viscera in part possible.

The significance of the respiratory act for the entire body has, accordingly, experienced a considerably changed point of view in recent years and it is therefore advisable at first to review briefly the form and effects of physiological respiration.

All the parts of the thoracic cage are almost never used uniformly in respiration. More often the quiet respiratory activity takes place more at the caudal and lower portion of the thoracic wall, except in the various types of breathing (costal, abdominal, costo-abdominal), whereas in deep respiration the cephalic and upper portions of the thoracic wall are utilized chiefly. The significance of the variations lies in the fact that the respiratory movement of a portion of the thoracic wall affects only the portions of the lung in its immediate vicinity, whereas the more distant parts are left entirely unaffected, because the variations in pressure in the pulmonary tissue produced by the movement are propagated only in a limited area.

In quiet breathing, therefore, the pulmonary apices, as well as the hilus portion of the pulmonary tissue are almost never aerated. Nevertheless, they are adjacent to portions of the chest wall, which do not undergo any motion at all. Their aeration is made possible only by deep diaphragmatic breathing, namely, through the movement of the tendinous centre of the diaphragm (Keith).

In the lateral posture, that half of the bony chest wall upon which the person lies moves very little, but the corresponding half of the diaphragm, on the other hand, moves much more than in the upright position of the thorax. In contrast to this, the bony half of the chest wall "above" the part on which the patient lies moves much more than in the upright position, and the corresponding half of the diaphragm only barely as much as it is moved along with the other side. The respiratory movements of the diaphragm resemble the movements of a pendulum hung from the "upper" chest wall.

In the next place, the "size of the lung" should be considered as the effect of respiratory motion, that is, the result of the continuous filling of the alveoli with air, which disappears after a long continued cessation of the respiratory activity (atalectasis formation); also of the pulmonary "tension" produced thereby, which constantly endeavors to return the lungs to the fetal condition of airless balance and thus constitutes a powerful expiration power. In addition, the respiratory movement denotes the physiological growth stimulus for all parts of the respiratory apparatus, and it also influences the position of the same to a marked degree. This influence appears particularly prominent in the case of the diaphragm; it is less distinct but, nevertheless, well demonstrable in the case of the bony chest wall. In addition, there is the intrathoracic power of suction produced by the pulmonary tension, which constitutes a considerable source of power for the returning blood circulation. The portion of the diaphragm pierced by the inferior vena cava also plays an important part, inasmuch as it regulates the uniformity of the blood supply to the heart, and at the same time is the most important factor in the expulsion of the bile from the liver. The action of the diaphragm in conjunction with the musculature of the abdominal wall produces the effect of a massage of the abdominal contents, and also of a support for the abdominal circulation as well as for peristalsis. Furthermore, the absorption of the fluid (lymph and exudate) present in the lungs and pleura is favored by the respiratory movements.

These observations lay the foundation for the results to be expected from respiratory disturbances, and closer observation results in a much larger field of results from a pathological respiratory technic.

Let us first consider the functional disturbances belonging in this group. A most harassing cough develops when, instead of breathing through the nose, the patient breathes for a long time through the mouth, even though the oral opening is very narrow, because the air, without sufficient moisture and warming by the nasal mucous membrane, injures the ciliated epithelium of the deeper air passages, and produces drying of the mucous. An especially harassing cough occurs in the early morning hours, because the oral opening is constant and much wider during sleep. Increased temperature (fever) results from the respiratory activity of diseased portions of the lung, in proportion to the resulting increased resorption of the toxins accumulated in the vicinity of the disease focus and of products of degeneration (bronchiectatic cavities, tuberculosis, pleural exudate). Dyspnea results from an improper respiratory function, inasmuch as in air hunger the inspiration alone is regularly exaggerated, but not so with expiration; therefore the amount of the stagnating residual air increases; the inspired fresh air is utilized only very poorly and the "healthy" portions of the lung are injured (vicarious emphysema in pleurisy, tuberculosis, etc.).

Exaggerated function is supplied chiefly by the bony chest wall, especially in the upper portions, where only the inspiratory muscles are attached; the diaphragm, however, which has a powerful antagonist in the musculature of the abdominal wall, often remains unaffected, so that it is drawn upward even

on inspiration (inspiratory depression of the gastric groove) and with it even the dilatation of the thoracic wall is in part paralyzed. The air aspirated into the upper portions of the lungs remains permanently in the thoracic cavity and embarrasses the penetration as well as the utilization of additional inspiratory air.

With a unilateral change of the respiratory function as, for example, that due to bronchial stenosis, a difference in pressure between the two halves of the thoracic wall develops with every respiratory act. The halves of the thoracic wall are separated from each other by the soft mediastinal wall, which is moved from its place by the difference in pressure, and there results the röntgenologically demonstrable displacement of the mediastinum.

The tendency to catarrhs in the upper air passages should be considered as the result of habitual mouth breathing, because the injury of the mucous membrane of the deeper air passages (mentioned above) resulting from the mouth breathing, as well as the deficient utilization of the uppermost air passages, must result in a reduction of the powers of resistance. The insufficiently prepared air due to mouth breathing produces an irritation of the nerves of the mucous membrane, and, as mentioned, an irritative cough. A pulmonary distention always results from air hunger and irritation of the pulmonary branches of the vagus and asthmatic attacks are even a result of this vagal irritation.

The predisposition toward pulmonary tuberculosis, which develops as a result of insufficient respiratory activity in the pulmonary tissue, constitutes the transition to the next group because it is often associated with an organic disturbance. Owing to the loss of the respiratory activity, that is, of the physiological growth stimulus, there results an insufficient development of the thoracic walls—the socalled phthisis habitus.

Before discussing this predisposition toward tuberculosis, however, we must at least briefly discuss a functional disturbance which is often encountered, namely, the impossibility of assuming a lateral position for a long time (clinophobia). This disturbance, which is often observed after pleural involvement, particularly after the healing of emphysema, and makes sleeping particularly difficult, may readily be relieved by respiratory therapy. It is caused by an agglutination of the diaphragm to the lateral chest wall, through which the necessary change in the position of the diaphragm becomes impossible. As a result of their weight, the abdominal viscera fall upon the abdominal surface of that half of the diaphragm which lies close to the side lain upon, push the diaphragm against the thoracic cavity there, and at the same time draw the "upper" half of the diaphragm as much as possible downward. If the diaphragm is firmly adherent in its lower half, this organ, drawn tightly like a drumhead, is stretched by the encroaching abdominal viscera. But if the upper half of the diaphragm is attached to the thoracic wall at the phrenicocostal sinus, the angle of the diaphragm cannot be opened and the abdominal viscera which pull from below produce pain there. The development of organic changes due to respiratory disturbances were also unmistakably demonstrated, especially by the frequent observation of unilateral deformities occurring after gunshot wounds of the chest. With insufficient respiratory activity of any portion of the lung there results diminution of the lung's power of expansion (atelectasis).

From a diagnostic as well as from a therapeutic point of view atelectasis of the apices and hilus, respectively, produced by such disturbances, has special significance. This change, considered as specific, often prematurely, occurs particularly after pleurisy and pneumonia, because after these diseases the diaphragm, which should be considered as the respiratory motor for these portions of the lung (Keith), is paralyzed much less; but it is also found in other conditions as the result of painful changes in the thoracic cage. If the breathing becomes painful, as the result of destruction of tissue of the thoracic wall, for example, the patient helps himself by diminishing the intensity of the movement of the thoracic wall as much as possible and forces a flattening of respiration through the use of the mouth as an air passage.

Functional diagnosis, that is, the differentiation with the aid of suitable respiratory gymnastics, alone makes possible the important determination of specific and nonspecific changes, and also the important prophylaxis of a specific infection of a previously uninfected, but markedly predisposed pulmonary apex after pleurisy and pneumonia, respectively, as a result of a function which is diminished because not sufficiently supplied with blood and air.

Upon this dependence of the air filling upon the functional size depends also the formation of shadows at the hilus with insufficient activity of the diaphragm. It is only the displacement of the heart in the vertical direction, which occurs with increased movement of the diaphragm in association with a change in form of the mediastinal wall, that supplies the renewal of air in those portions of the lung which surround the heart. Naturally, there are also associated with this, inflammatory changes of the tissue, as, for example, irritation of the bronchial mucosa, produced by a functional disturbance as well (mouth breathing mentioned above). With increased activity of the lungs, however, their air content is permanently increased and, consequently, there develops an enlargement (emphysema, increased pulmonary volume). In the same way the rapidity of the disappearance of pleural exudates depends upon the liveliness of the respiratory activity on the part of the portions of the thoracic wall surrounded by the fluid, and, accordingly, the permanency and induration of the same in the basal portions of the diaphragm (as a result of the continued low position and functional inhibition produced thereby), especially the portion lying between the base of the lung and the upper surface of the diaphragm. Even the externally visible changes of body formation, socalled pathological habitus, of the thoracic cage, and the formation of the face may be shown to be the result of a changed respiratory technic. Drop shoulders, flattening and protrusion, respectively, of the walls of the thoracic cage, as well as kyphosis and abnormal flatness, respectively, of the thoracic portion of the vertebral column and scoliosis of the same represent the sequelae of an increased or decreased activity, respectively, of the

respiratory musculature and also, especially, of the corresponding changes in their tone produced thereby.

The swelling of the legs as well as of the abdominal organs with deficiency of respiratory activity of the diaphragm and abdominal musculature constitute an additional organic change. These form such an important aid for the efferent circulation from the lower half of the body as to produce organic changes.

The displacement of the mediastinum with its consequent changes of form and stasis in the peripheral organs develops on the same principles, even though there is a difference in the tension in the two lungs. With a rightsided exudate there results a marked concave distortion of the venae cavae toward the right with marked kinking of the inferior vena cava at its perfornation of the diaphragm and indentation of the lumen of the superior vena cava in proportion to the displacement of the heart toward the left without simultaneous turning of the same. On the other hand, such a twisting does occur in the sense of a rotation around the site of exit of the large arteries, whereas the site of entry of the inferior vena cava turns from the left and posteriorly toward the right and anteriorly. The apex of the heart is turned anteriorly, which results in strangulation of the aorta and more often in strangulation of the pulmonary artery. In addition there is a sabrelike indentation of the latter previous to its division and further dorsally of the arch of the aorta, as well as a straightening of the cavae in the presence of a long existing exudate and induration formation (Gräff).

With continued mouth breathing the effect of the muscular tone of the lips is lost to the teeth and force is exerted by the pressure of the tongue acting from within: the teeth are pushed outward and become prominent. The lips and nose show the effects of a deficient lymph and blood return, which results from the deficient suction of the flattened mouth breathing and they become thick (scrofulous)—signs which usually give rise to the reverse conclusion, namely, that of malformation making the utilization of the physiological nasal air passage impossible.

As a result of the diminished activity of the diaphragm, which squeezes the liver by its contraction, like the hand squeezes a sponge (Wenckebach), there occurs enlargement of the liver as a sign of the stasis of blood, lymph and bile, as well as with persistent duration of the same, of a tendency to cholelithiasis (Naunyn). The stasis in all of the abdominal viscera resulting from the deficient respiratory activity of the diaphragm and the abdominal musculature, is easily understood in this way—motor gastrointestinal insufficiency.

On the other hand, the respiratory activity in lungs affected with tuberculosis produces emaciation in proportion to the absorption of toxic decomposition products favored thereby as an organic change.

These observations, based upon theory, allow the following conclusions to be drawn: The changing of the respiratory activity in the sense of a return to its form and intensity in the healthy person must produce a return or avoidance, respectively, of those disease symptoms which are produced by the change (increase or decrease) of the intensity, respectively, by the change in the respiratory form. *Cessante causa, sollitur effectus.* In such cases the change in respiration denotes etiologic therapy. The more pronounced use of respiratory movements for the purpose of a support for the insufficient powers, wherever the latter are not caused or produced by the respiratory activity (for example in the circulation) denotes a utilization of the respiratory powers in the sense of a compensatory therapy.

(*To be concluded*)

Action of Radiations on Tissues.—C. P. G. Wakeley (*British Journal of Surgery,* July, 1924) concludes from his experiments that as regards the mode of action of radiations upon living tissues, various views have from time to time been put forward, such as that the radiations decomposed the lecithin present in the tissue cells, and that its disintegration products acted in an ingenious manner. As a matter of fact this action upon lecithin has not been substantiated by subsequent research. Another view is that of specific activation of intracellular enzymes. Here, again, most recent investigations fail to demonstrate any such action, and experiments at King's College Hospital upon the oxidases, lactase and tyrosinase fail to show any effect as to sequel to irradiation. Probably no one theory can explain all the phenomena; but what does seem clearly established is that x rays and the gamma radiations from radium have a marked effect upon certain classes of colloids, among which are proteins and starch. Proteins undergo a marked diminution in viscosity, and are more easily precipitable after a radiation than before. In the case of starch, as shown by Colwell and Russ in 1912, this undergoes at any rate a partial change into soluble starch and dextrin. It seems not improbable that certainly one of the effects of radiation is disturbance of the colloidal equilibrium of the cells, with subsequent devitalization. If not carried too far the cell may recover, but if certain limits be exceeded the damage is irreparable, and the intracellular enzymes may then come into play, their action being of a destructive character upon the devitalized cell protoplasm.

Intravenous Injections with Blocked Reticuloendothelial System (Blockage Therapy).—Paul Saxl and Ferdinand Donath (*Wiener klinische Wochenschrift,* June 26, 1924) investigated the result of injections of colloidal silver on subsequent infusions of other substances. An intravenous injection of 10 c. c. of electrargol, which was administered ten minutes previous to an injection of water, dyestuffs, adrenalin, or of argochrome showed that the latter substances were retained in the blood for a longer period of time. In this way it is actually possible to accomplish a blockage of those organs, which otherwise retain all substances that are injected into the blood. Apparently this functional blockade shows at first only a specific character. Undoubtedly this established principle may have a great significance for intravenous therapy under certain conditions, as when it is desirable to keep injected substances in the blood for a long time, namely in blood infections in which the bacteria in the blood are to be attacked. The authors call this therapeutic procedure "blockage treatment."

The Height and Duration of Fever in Relation to the Clinical Outcome in the Treatment of General Paresis With Malaria*

HENRY A. BUNKER, JR., M.D.
and GEORGE H. KIRBY, M.D.
New York

General paresis, it needs scarcely be said, is a condition of the utmost gravity—the more so that in the great majority of cases it yields to arsenical treatment, if at all, only when that treatment is of the most intensive sort, including often of necessity the intracisternal and the intraventricular employment of the Swift-Ellis technic (1) in addition to its routine lumbar use. A new method of treatment of this disease, that of inoculating the patient with tertian malaria, as first practised by Wagner von Jauregg in 1917, has meanwhile entered the field and has seemingly justified itself in its ability to produce complete clinical remissions—*cito, tute, jucunde*—in some thirty-five per cent. of unselected cases of general paresis, according to the now rather extensive experience of workers abroad (2, 3) and to our own (4), and in a considerably higher proportion than this of early cases of the disease.

In combating a condition characterized by as ultimately hopeless a prognosis as is general paresis, it might be thought that to take into too serious account the dangers attendant upon the method of treatment employed bordered almost upon the irrelevant—"for extreme diseases, extreme methods of cure," in the Hippocratic aphorism; and it might, indeed, be held that even if treatment by inoculation with malaria were many times more radical and fraught with risk than would seem actually to be the case, it would still be a wholly justifiable procedure in the light of the fact that not infrequently it can achieve results which can otherwise ordinarily be attained only at the cost of infinitely greater trouble and consumption of time.

At the same time it would be absurd to maintain that infection with even a benign form of malaria differs from many another therapeutic method in being free from all risk whatever; and it is the purpose of this paper to point out in a tentative way the extent to which account should be taken of the fact that although a no more than transitory disturbance of the body economy seems, in the great majority of cases, to result from the pyrexia of almost unexampled height which infection with inoculation—malaria may produce, there remains nevertheless the occasional case in which contingencies ordinarily more or less remote must be kept in mind, such as the possibility of lighting up a quiescent tuberculous process, the possibility of producing severe hematuria, even the possibility—as yet open to considerable question, it must be admitted—of inducing a paretic convulsion (4), in addition to the occasional complications which have been encountered in the more extensive experience of certain European observers (5). Such possibilities, relatively remote though they may be in general, occasionally suggest themselves more forcibly than would ordinarily be the case; the personal responsibility assumed by the physician would obviously be rather greater than ordinary, for example, in the instance of an early, more or less nonpsychotic case of general paresis in which the desire to combine efficiency of therapeusis with economy of time might conceivably prompt the use of malaria treatment *ab initio*, with the postponement of the much more protracted arsenical therapy until afterwards. Finally, it is not without significance that—at least so far as our own experience is concerned—such few complicating features as we have so far encountered have made their appearance only after the seventh or eighth malarial paroxysm, or even later. It is on the ground of these several considerations that it has seemed to us possibly worth while to inquire as to the smallest "amount of malaria," so to speak—that is, in terms of both height and duration of pyrexia—which would produce, in the treatment of paresis, the results which have been seen to follow upon a more severe and protracted febrile reaction, and so to determine with some approximateness the minimal febrile response consistent with the assurance that the treatment has exerted its full beneficial effect.

The customary employment of nine to twelve febrile paroxysms in the majority of our patients before terminating the malarial infection with quinine

*From the Psychiatric Institute, Ward's Island, New York.

has resulted in wide variations among these patients in their total febrile response as measured by the entire number of hours during which the temperature has remained above a given level, such as 104° F. or 105° F. In one patient, for example, who had eleven malarial paroxysms, the temperature remained above 104° F. for a total of ninety-two hours for the eleven paroxysms, whereas in another patient, inoculated with the same strain of plasmodium, and subjected to an equal number of attacks of malaria, the temperature remained above 104° F. for a total period of only thirty hours. It therefore seems reasonable to express the febrile response in terms of the number of hours during which a given height of temperature is maintained, rather than as the mere number of malarial paroxysms which the patient is allowed to have; and at the same time it appears natural to inquire whether a reaction such as that of the latter patient is not fully as therapeutically effective as the much more severe pyrexia undergone by the former, even though, as should be borne in mind, there exists no certainty that in the elevation of the body temperature lies the *modus operandi* of the malaria treatment of general paresis.

If we select from among the eighteen patients elsewhere described (4) who, following upon treatment with malaria, exhibited a remission complete enough to make possible their discharge from the hospital and subsequent return to work—if we select from among these the patients who showed relatively the smallest total febrile response, we find that two of them maintained a temperature of 105° or higher for a total of only five hours, another for six hours, another for seven hours, another for eleven hours, two each for fourteen hours, two for sixteen hours and three for seventeen hours all told. Six of these twelve, although reaching a temperature of 106° F. in one or more attacks, did not maintain this temperature for one full hour continuously in any one of them; while of the other six, three patients maintained such a temperature for a total of only one hour, one patient for two hours, and two patients for but three hours out of the entire course of their malarial treatment.

Hence it may be concluded, at least provisionally, that it is not necessary that a temperature of 106° be maintained for even as little as one full hour, since six patients who failed to do so nevertheless came to exhibit good remissions (excellent in three of these), and three additional patients achieved a similar clinical outcome after maintaining such a temperature for a single hour only out of the sixty to eighty hours in all during which their temperature was distinctly elevated; while even three hours as the total period during which the temperature remained at 106° or higher seems insignificant in comparison with the total periods of eleven, thirteen, fourteen and even seventeen hours (at 106° or over) registered by a number of patients in our series.

We can deduce with rather less certainty, however, the requirements in the case of a temperature of 105° F. Because two patients attained a singularly complete remission after a total of only five hours, throughout their entire course of malaria, during which the temperature was 105° or higher, and another obtained an entirely similar result on the basis of but seven hours altogether of pyrexia of this grade, it does not follow, of course, that intervals as brief as these would necessarily suffice in every case. But it is most probably of some significance that twelve patients (out of eighteen) managed to secure a good remission after a total of seventeen hours (or less) of a temperature of 105° or higher, and seven of these twelve after a total of fourteen hours or less.

It may be objected that these cases were of especially short duration at the time of treatment, and that accordingly a smaller amount of treatment was effective than would have been necessary had the cases been more advanced. To this it can only be replied that these twelve patients represented among them various stages in that degree of advancement beyond which it is for the most part impossible to obtain remissions at all; three of these twelve patients, for example, were as advanced at the time of their commitment and admission to the hospital as any in whom to date we have been able to obtain a good remission.

Nor are the results in question due solely to the clinical type of paresis which these patients represented; far from belonging without exception to the manic type which in our experience offers the best prognosis as regards the eventual occurrence of a remission, four of these twelve patients were of the expansive type and two were of the simple dementing type—in fact, the only two cases of this type in which we have so far obtained a good remission (4). Since, then, those factors which are in all probability of considerable importance in influencing the occurrence of a favorable clinical outcome were present in these twelve patients in an extremely variable degree, so that the group as a whole cannot be regarded as in any known respect unusually susceptible to therapeutic influence and therefore requiring treatment of less than ordinary intensity, it seems reasonable to infer that a temperature of 105° maintained for a total period of at most eighteen hours, and possibly of not more than twelve hours in all, will undoubtedly accomplish all that a more protracted period of fever of this height would do—an inference which is lent some further support of a certain kind by the fact that pyrexia of this degree maintained over total periods three times as long has not availed to bring about clinical improvement in a considerable number of other patients.

For the fact is not to be lost sight of that there are other factors than simply intensity of febrile reaction which determine whether or not a clinical remission is to be obtained in a case of general paresis treated with malaria—factors such as duration of the disease at the time of treatment and its clinical type, for example, and in all probability still others whose character is at present wholly obscure; so that it is only suggested in the present connection that a certain height and duration of pyrexia, which we estimate conservatively at 105° for a total period of not more than twelve to eighteen hours, will be as effective as an increased period of fever of this degree in attaining a favorable clinical result in such cases of general paresis as are still capable of a therapeutic response.

To say, however, that it is not necessary to produce or maintain a temperature of 105° at all would savor of defining the critical temperature above which remissions may be obtained in suitable cases.

but below which it is impossible to bring them about, and this we are far from being prepared to do. Since none of our cases has exhibited a temperature of 104° without at the same time (as has been seen) mantaining a temperature of 105° for at least five hours out of the total duration of the malarial pyrexia, we are not even able to estimate the total number of hours during which it is necessary that a temperature of 104° be maintained in order to produce a favorable result. We can only say that in four of our patients showing good remissions a temperature of 104° and higher was maintained for a total period of only nineteen hours but whether this period of fever of this degree would alone have sufficed, without the five or more hours during which, in addition, the temperature was sustained above 105°, we have no means of knowing. If the behavior of other strains of plasmodium should prove similar to that of the two which we have so far employed, this question, indeed, will scarcely arise; given the presumption that a temperature of 105° maintained over a total period of not less than twelve hours will accomplish all that may be effected by a more protracted period of fever, the only question of practical import will be whether five or six malarial paroxysms will not, if the plasmodium in use be sufficiently "virulent," fulfill this requirement, making unnecessary the nine to twelve febrile crises which have constituted the routine procedure in the past.

SUMMARY

1. Although the malarial treatment of general paresis cannot be regarded as a hazardous or particularly radical mode of therapy, cases at times occur in which it is desirable to know the minimum degree of febrile response, as regards both height and duration of pyrexia, which is consistent with the maximum therapeutic effect of which this method of treatment is capable.

2. Four of our cases of general paresis have achieved good remissions, two of these excellent remissions (all of them now of more than a year's duration), in whom a temperature of 105° was maintained for a total period of not more than five to seven hours, while in twelve such patients this total period did not exceed seventeen hours, being materially shorter than this in seven of these twelve cases.

3. Our data do not permit the statement that a total febrile reaction of much smaller intensity and duration than the foregoing would not serve as effectually in accomplishing the same clinical results; but in the meantime it seems safe to conclude that a temperature of 105° maintained over a total period of not more than twelve to eighteen hours will give rise to a favorable outcome, among unselected cases of general paresis, as readily (and with proportionately diminished risk to the patient) as an equal or greater degree of pyrexia maintained over a greater number of hours.

The Treatment of Paresis by Malarial Infection*

GEORGE B. LAKE, M.D.
Chicago

A hundred years ago paresis was a comparative rarity, but, of late, it is becoming so common, and the manifestations of the disease are so appalling, especially to the family and friends of the patient, that, in view of the gloomy prognostic picture painted by the authorities, any form of treatment which offers a prospect of ameliorating or controlling the condition is worthy of careful study.

No attempt will be made in this paper to discuss the etiology, pathology, symptoms or diagnosis of paresis, as these are well known to you all. We will briefly consider the prognosis and treatment, as outlined in the textbooks, as a background for what is to come, and then give a short résumé of the literature in English, upon the subject of one of the newest plans of treatment which seems to offer considerable promise.

This paper offers no new contribution to the literature of paresis, and is prepared solely for the reason that I, having facilities for reviewing the literature, have felt that a résumé might be of service to those whose time or library facilities are limited.

Starr (1) says that the prognosis in paresis is "absolutely bad," and recalls that Krafft-Ebing never saw a recovery in two thousand five hundred cases. As to treatment, he remarks: "No form of treatment will arrest paresis"; but suggests that the arsenicals, absolute abstention from business or excitement and symptomatic measures should be tried.

Jelliffe and White (2) call attention to the fact that remissions lasting for six months or more not infrequently occur, but that these are invariably followed by relapse and death.

Burr, in his translation of a two volume work by various noted German psychiatrists (1915, p. 711) states that this disease is "incurable and progressive," though remissions of some duration do occur.

In connection with the subject under discussion, it is of interest to note that the early work along this line was done in Europe, and that in this, the only

*Read before the Staff Conference of the Norwegian-American Hospital, Chicago, March 7, 1925.

German textbook consulted, there occurs the only reference found to the fact that, following acute febrile affections, the paretic may be surprisingly improved.

As to treatment, the authors offer nothing else which is new; antisyphilitic remedies, rest, confinement and symptomatic treatment being suggested.

Church and Peterson (3) declare that the authors have never known of a patient recovering, and that, in the twelve cases of recovery reported in the literature up to that time, it is their belief that the disease was wrongly diagnosd. Their recommendations as to treatment offer nothing in addition to what was suggested by the other authors quoted.

Against this gloomy background, we turn with a feeling of relief to the modern literature, where we find two methods of treatment under investigation which seem to hold out a measure of hope to the unfortunate sufferers from paresis. These methods consist in the administration of tryparsamide, and in infecting the patient with malaria, the latter of which will now be briefly considered.

In referring to the literature in German, the name of the author and the date will alone be cited, as bibliographies will be found connected with the articles in English.

The general idea of the nonspecific treatment of paresis was first announced by Wagner von Jauregg, so long ago as 1887, and he followed this up with other and later observations, which were repeated and confirmed by Pilcz in 1911.

In 1917, von Jauregg inoculated nine paretic patients with the blood of another patient suffering from tertian malaria, with results so far favorable, in the six cases which were not very far advanced, that, four years after the conclusion of treatment, three of the six patients were still actively at work.

In 1923, Kirschbaum reported a series of 196 cases, of whom sixty-one were classed as having complete remissions; while Gerstman, in 1922, reported 294 cases, of whom 112 were considered as having "good remissions."

A. R. Grant and J. D. Silverston (4) report the serological findings in forty cases treated by malaria, and in every case found some improvement. In 91.9 per cent. of the cases, the lymphocytes in the cerebrospinal fluid were diminished and in forty-nine per cent. the protein content became less; the blood Wassermann reaction was diminished in intensity in sixty-five per cent.; all three of these changes occurred in forty per cent. of the cases.

Warrington Yorke and J. W. S. Macfie (5) report results of inoculation of patients with tertian and quartan malarial parasites and also of controlled infections by bites of mosquitoes. These observers treated eighty-four cases of paresis by malarial infection, of which twenty-three showed such marked mental and physical improvement that they could be discharged from the mental hospitals; in ten there was definite physical improvement but no change in the mental condition; and in seventeen there was great physical and distinct mental improvement—a total of fifty patients improved.

Grant and Silverston (6) report fifty cases treated by this method since July 31, 1922, with tabulated data of the control of the malarial infection. Of these fifty patients, seven are reported as "completely recovered," having regained their full working power, while thirty-three have shown partial remissions.

Lewis, Hubbard and Dyar, of St. Elizabeth's Hospital, Washington, D. C., (7) have contributed an exhaustive and scholarly article, dealing with the history of the treatment of paresis; the history of the malarial infection treatment; and including numerous illuminating charts, graphs, tables and macroscopic and microscopic photographs. There is also a bibliography of sixty-seven references. These observers report fifty-one cases which were carried through a complete period of observation, of whom fifteen were reported, after exhaustive and critical study, as "complete remissions."

W. M. McGrath (8) reports a case in which the patient was completely relieved of the gastric crises of tabes by malarial infection.

Professor Wagner-Jauregg (9) reviews his earlier work and methods and reports a series of two hundred cases treated by this method, with fifty complete remissions, to the extent of permitting the patients to return to their former occupations.

In the same number of the same journal in which Dr. Wagner-Jauregg's paper appears, Dr. H. F. Delgado reports four cases, with complete remissions in two.

The most recent and easily available communication on this subject is by Bunker and Kirby (10). These authors review the literature, with a bibliography of twenty references (mostly in German) and add a report of fifty-three patients treated by this method, of whom seventeen have been discharged from the hospital as complete remissions; fourteen of these seventeen have returned to work.

The method of treatment given by these latter investigators consists in the inoculation of the patients by the intravenous injection of from one to 1.5 c. c. of typed, citrated blood from another patient, already under treatment, who is infected with tertian malaria. It has not been necessary to draw the blood from the donor during a paroxysm.

After an incubation period of from three to seven days, the patients begin to have typical malarial attacks, every other day or every day, and they are permitted to have from eight to twelve of these attacks, after which the malarial infection is controlled by giving ten grains of quinine, three times a day, for one week.

In eighty-two per cent. of these attacks the fever rose to 104° or higher; in sixty-nine per cent. to 105° or higher; and in forty-seven per cent. to 106° or higher.

The attacks of inoculation malaria proved to be more readily and promptly controllable by quinine than is usually the case with spontaneous attacks, resulting from the bites of mosquitoes. They find that there is no parallel between the clinical and serological results. Cases with the most definite and complete clinical remissions frequently show little or no change in the spinal fluid findings; while three cases where the spinal fluid became completely negative showed no clinical improvement whatever.

It is of interest to note that the clinical improvement of patients treated in this manner continues to progress for a number of months after the malarial infection has been controlled, so that results

reported less than one year after the cessation of treatment show less than the maximum improvement to be expected in a series of cases.

For those who read Spanish, two references not found in any of the other bibliographies studied are to be found in the articles of Merzbacher (10) and Sierra (11). The bibliography appended to this article is by no means complete for the literature in English, but cites only a few of the most readily accessible, representative and complete articles.

While no deaths have been found recorded which were directly and wholly attributable to this method of treatment, it is not at all improbable that a fatal outcome, in some cases, might have been more or less indirectly hastened by the severity of the malarial reactions.

SUMMARY AND COMMENT

1. Prior to the recognition of paresis as a syphilitic disease, the prognosis for recovery, or even for any reasonably complete or permanent improvement, was absolutely hopeless.

2. The recognition of the syphilitic nature of paresis and the advent of the modern methods of antiluetic treatment did not materially improve the gloomy character of the prognosis.

3. The method of treating paresis by infecting the patient with malaria rests, at present, on a wholly empirical basis, but present no great difficulty in its performance. The only basis for the results obtained seems to be connected with the hyperpyrexia produced by the malarial infection.

4. In the few articles here abstracted, there are reported 941 cases treated by this method, of whom 291, or 30.9 per cent., showed what were classified as complete remissions, most of these patients being able to return to their former occupations. The writer knows of no method for treatment of this disease showing comparable results.

5. The malarial infection may submit the patient to a possible danger of shortening his life, but, in a condition whose prognosis is so generally recognized as hopeless under older methods of treatment, it would seem that the possibilities for relief more than outweigh the not improbable chance that an already blighted life may be shortened.

General Paresis and Its Treatment With Malaria

HERMAN GOODMAN, M.D.
New York

It has been known for a long time that remissions of chronic disease may occur after attacks of an acute specific fever, or long continued suppurative processes. However, only recently has any really startling effect been wrought by the induction of acute fever in persons suffering from what has been regarded as an incurable disease.

Clinical cutaneous syphilis was recognized in Europe about the time of the return of Columbus (it is not definitely determined that the disease was carried to Europe by his sailors, however). The fact that syphilitics may later show nervous disease due to their general infection was not recognized until more recent times. The actual description of general paralysis with its intimate connection with mental deterioration was likewise unrevealed until not more than a century ago.

General or incomplete paralysis and disorder of the mind developing side by side and caused by chronic arachnitis (inflammation of the middle layer of the covering of the brain); in other words, that these two phenomena were the associated symptoms of a definite disease having a distinctive pathological anatomy was the contribution of A. J. Bayle. This opinion had never been previously expressed by anyone, and it has since been satisfactorily proved to be true in its essentials. Eminent neurologists have expressed themselves publicly as believing that the recognition of the association of the two orders of symptoms signalized the greatest advance ever made in the history of mental diseases.

The first suggestion of possible recognition of general paralysis of the insane is generally attributed to Willis in 1581.

The first case of undoubted general paresis recorded in medical literature was described in 1798 by John Haslam. He was apothecary to Bethlem Hospital, one time president of the Edinburgh Royal

Medical Society, and one of the original members of the Medicopsychological Association of Great Britain and Ireland.

Haslam's celebrated case was a man infected with syphilis while traveling abroad, and he had the typical delusions of grandeur. He considered himself at times the King of Denmark, and at other times the King of France. Ignorant, he professed himself master of all dead and living languages. The physical findings, the speech defects and the deterioration were noted.

Alcohol, venereal excesses, and anxieties were thought to be the cause of general paresis at this time. Clear cut descriptions after Haslam but without hint of the true etiology were given by Georget and Focelle, and Delage among others.

Bayle's contribution which has merited for him the designation of Bayle's disease as the eponym for general paresis, deserves further mention now. Bayle commenced the study of medicine in Paris in 1815, when he was only sixteen years of age. He early concluded that mental diseases depended for their elucidation on anatomical and pathological researches. He performed over four hundred postmortem examinations in less than five years. The thesis by which his work has come down to us is *Recherches sur les maladies mentales* submitted to the faculty of medicine at Paris in 1822. Bayle did much more work, wrote numerous monographs, and died in 1858. A recent publication was the *Centenaire de la Thesis de Bayle* (1822-1922) published in Paris. Bayle gave an accurate and almost complete account of the description of the pathological anatomy of general paresis. The inflammation of the meninges which he discovered he named chronic arachnitis.

No special advance in the study of paresis was made until Fournier on the basis of his exceptionally wide and long continued observations hit upon the mistaken theory of parasyphilitic diseases. Fournier gave the world the conception of diseases in which syphilis was the essential cause, but which were not the direct result of the syphilitic infective agent. General paralysis headed the list which was regarded as parasyphilitic. It must be borne in mind that Fournier did not have the advantage of the work of the bacteriologist, of the serologist, and the histopathologist who since Fournier has passed to the great beyond have given us the spirocheta pallida, the Wassermann test, and technic for the demonstration of spirochetes in the brain tissue. Although Esmarck and Jessen, and later Kuelberg were probably the first to call attention to the fact that general paralysis occurred especially in persons who suffered from syphilis, it was as a direct result of Fournier's work that Krafft-Ebing gave the famous dictum, "General paralysis is a product of syphilization and civilization."

It was then practically in our own time that the syphilitic causation of general paresis was proved. Only as recent as 1915, Nonne in his *Syphilis and Nervous System* devoted more than fifty pages to the consideration of the relation between syphilis and paresis. The Wassermann test opened a new field for speculation. Noguchi and Moore discovered spirochetes in the brain of persons dying of paresis, a finding confirmed by many; and Wile at Ann Arbor, and Forster in Germany, demonstrated spirochetes in the tissue taken from the brain of living paretics by puncture. Chemical, serological, and cytological formulæ have been elaborated which are almost infallible in the laboratory diagnosis of paresis by examination of the fluid withdrawn from the spinal canal.

The best treatment for general paralysis of the insane is preventive treatment. The modern dermatologists and syphilologists all are trained in the proper technic for the recognition clinically and serologically of symptoms indicating present or future brain and nerve involvement of the syphilitic patients under their care, before they become paretics.

The drugs used in the modern treatment of syphilis, namely salvarsan and its modifications; mercury in its various forms; and the iodides may in many cases complete a cure of the infection. In other patients, the brain is infested with the parasites and despite every therapeutic measure the symptoms of general paresis appear.

With the improvements in medicinal technic, and the utilization of Quinck's lumbar puncture procedure, we have within recent years attempted to reach the brain through the meninges and have introduced modified solutions of salvarsan by way of the spinal cord coverings. Enthusiasm for this form of therapy has not been sustained, and the syphilologist has welcomed another mode of attack on general paralysis.

As early as 1816, it was noted that cases of general paralysis frequently showed remissions of symptoms, and that often apparent cures were established following febrile illnesses. In an attempt to simulate the general reaction of febrile diseases, various substances have been injected into patients suffering from paresis. Chemical substances have been tried and discarded. Toxalbumins such as tuberculin have also had a trial. In 1917, Wagner-Jauregg inoculated nine patients suffering from general paralysis of the insane with blood withdrawn from a patient with benign tertian malaria. Six of the patients showed favorable results. This is about what happened. Two to four cubic c. c. of blood were withdrawn from the vein of the untreated malaria patient during a paroxysm, and immediately injected into the subcutaneous tissue of the buttock of the paretic. After a free period of from eight to twenty-eight days, the injected patient evidenced the chill and fever of a malaria infection. The patient was allowed to have eight to twelve chills, when malaria treatment in the form of quinine was administered. The quinine treatment of this artificial malaria is extremely effective, and no recurrence has been noted. Neosalvarsan or silver salvarsan may be administered intravenously during the period of quinine injection, but this has not been a regular feature of the treatment. The blood of the injected paretic shows the malaria parasite no different from those found in malaria acquired through the more natural channels, the mosquito bite.

Following the paroxysms of the febrile reaction to the malaria infections, the paretic shows a change for the better in no less than thirty-eight per cent. of the cases, and there is promise of much higher percentages of improvement, if not practical cures in the future.

It may be difficult in some communities to start the

malaria form of treatment because of the absence of malaria patients. Once obtained, however, the strain may be carried as long as patients are available to whom the blood of recently injected paretic malaria patients may be given. It has been found that the injection of syphilitic blood from one paretic to another has added nothing to the blood of the transferee.

I wish now to mention an observation which I have as yet not seen given in the literature on the malaria treatment of paresis. In the earlier days when clinical observation and tabulation of data were more carefully done than in our own hurried and laboratoried period, it was common to find the text books name certain regions of the globe apparently free from the nervous involvement of syphilis, although syphilitic infection was common enough in those same localities. The tropics have been noted for the absence of nerve involvement of syphilis. The reason may be but a natural malaria treatment, for as every one knows, the resident of the tropics rarely escapes malaria infection. Another possibility opens before us. Has transmutation been possible from the spirochete which causes frambesia, a disease of the tropics, simulating syphilis in many many respects but differing from syphilis in the absence of nervous complications, to the spirochete pallida of syphilis? Has the possible symbiosis or living together of the spirochete and the malaria plasmodium given us frambesia or yaws in the tropics? Has this same spirochete in the absence of the malaria plasmodium given the world syphilis? In this connection it should be remembered that the first observation of the disease which is regarded now to have been the one imported to Europe by Columbus's men was named to include the term *boubas;* a word used in the old Spanish records of tropical America to mean frambesia.

The remissions following the malaria treatment should of themselves not be regarded as anything especially new. Remissions in paretics are as old as the disease itself. In fact, in the first recorded case the patient was improved to such a degree that he was discharged from the detention home, only to return much deteriorated at a later date to die a paretic. The problem of remissions in paretics has been a difficult one. Has malaria given us an accidental remission? The observers, all enthusiasts, are certain that the remissions follow the malaria febrile disturbance of the entire organism, that the remissions are more marked, more certain, and actually last longer. Discharged paretics return, but the period of freedom has been longer. Some paretics have died paretics after the malaria form of treatment, and some have died of intercurrent infection apparently free of paretic symptoms. The histopathology of the brain substance of the treated cases of the later type has revealed the picture of the socalled stationary type of paresis described by Alzheimer. The blood and spinal fluid may continue to give the positive serological and chemical tests of paresis after the clinical improvement has been established. The physical findings may be markedly diminished.

The story then is that by artificial inoculation of malaria and the production of an infection of the blood cells leading to marked body reactions accompanied by paroxysms of fever, the symptoms of general paralysis of the insane are mitigated. The how of the treatment is yet unknown.

Psychoneuroses in Relation to General Medicine*

ALFRED GORDON, M.D.
Philadelphia

In order to understand the relation of psychoneurotic manifestations to clinical medicine in all its ramifications one must endeavor first of all to form a clear conception of the underlying factors capable of producing functional disturbances in the domain of the nervous system. Not infrequently it happens, as we all know, that when in a patient there develops for any reason at all subjective disturbances referable to the ear, nasopharynx or larynx, the otolaryngologist is consulted first. Should the subjective disturbances have an apparent relationship to the function of the ovaries, or to that of the vesical and biliary organs or of other abdominal viscera, to the function of respiratory and cardiac organs, to the function of the eyes—in all such cases the respective medical or surgical worker will be consulted first. Such an attitude on the part of the lay patient is psychologically logical and correct. But from a medical viewpoint, as we know, this attitude not infrequently leads to serious errors. That is to say, there are disturbances which have no fundamentally serious relationship to any given abdominal or thoracic viscera, but belong to purely mental functions which for reasons of a psychic character dissociated the work of various elements which enter in formation of harmonious display of organs and tissues. What precisely characterizes the patient in all such cases is not the multiplicity of symptoms, not the innumerable functional disorders which may simulate organic diseases, not the painful sensations which he or she experiences, but only a special state of mind, a special mentality.

Human machinery is so complex in its various operations that every one of us, otherwise sound, experiences now and then some indication of a functional disorder: either there is a gastric manifestation, or a vague pain, or a cardiac palpitation or a fugacious neuralgic discomfort. But being normally constituted, we give all such symptoms their proper interpretation, our attention is not firmly arrested on them, we continue our activities in spite of them. Furthermore, we are able to overcome unpleasant circumstances which may arise at any time, we may even surmount obstacles of a most serious nature.

*Read before the Section on Medicine of the College of Physicians on October 27, 1924.

Our relative indifference to all such conditions constitutes a normal state of mental health.

On the other hand the persons whose attention is held firmly and for a prolonged period of time by those subjective disturbances enumerated above, who view the least unpleasant event as a catastrophe, in whom there develop obsessive ideas and hold on to them for months and years, whose association of ideas is such that fears, anxiety and abnormal inhibitive or abulic phenomena make their appearance with the greatest facility and ápropos of insignificant occurrences, whose suggestibility and autosuggestibility are exaggerated, whose reactions to external or internal stimuli are intense—all such personalities present a type a part, an abnormal type of humanity and therefore require special consideration.

Some fuller elaboration of this category of individuals is now indicated for a clearer understanding of the subject under discussion. First of all, psychoneuroses should be firmly distinguished from mental deficiency. The latter is usually congenital and inherent and is the direct result of a morphological or physiological abnormality of the nervous structure. Of course psychoneurotic manifestations may appear in mentally defective individuals, but there is no unusual relationship between the two and we are considering here only intellectually normal cases. Psychoneuroses are fundamentally psychogenic and develop in the midst and because of abnormal psychological experiences. Before discussing these experiences, let us present a few examples of psychoneurotic manifestations.

CASE I.—One female patient, aged twenty-eight, following a normal confinement with no undue loss of blood and with a prompt recovery, misinterpreted her slight serious vaginal discharges which she explained to herself as due to a serious affection of her genitalia. Otherwise perfectly sound she consulted a number of gynecologists, who treated her by various methods and two of whom performed curetting. The woman became much depressed, she felt very unhappy and was in constant fear of malignancy without an actual physical constitutional basis for it. Subsequent events proved that her belief was only psychogenic, as she made a complete recovery under a psychotherapeutic management.

CASE II.—A young married woman aged twenty-five, was suffering from chronic constipation. She would occasionally have headache. Coming frequently in contact with a female friend who also had headache and who attempted to commit suicide in a fit of jealousy of her husband, in my patient there developed an idea that her friend became insane because of the pain in the head, and that therefore her own headache might in the future lead to the same consequences. She was in constant fear of such a termination. She was advised to consult an oculist, who promptly refracted her eyes and told her that the proper glasses would cure the condition. For two years she was in a state of fear and anxiety without any relief. She consulted a gynecologist, also a general surgeon at different periods. The former curetted the uterus, the second operated for suspected adhesions of the transverse colon. Neither the glasses, not the curettement, nor the operation on the colon removed the original mental condition, although every one of the three men assured her that the removal of the condition which they considered respectively as the sole morbid cause would undoubtedly bring about a complete cure. Under psychotherapeutic measures during a short period of time the fear and anxiety as well as the slight headache have all disappeared.

CASE III.—A young man of twenty-five, during a period of three years complained of disturbances referable to almost every organ in his body. At first it was the heart, then the gallbladder, then the nasal cavities, the ears, the eyes, the genitalia, rectum, and finally the right hypochondrium. Numerous physicians in and outside of hospitals were consulted and everyone advised and actually performed some manipulations or small operations. Some of them advised gross abdominal operations. For the last of his multiple complaints a surgeon advised an appendectomy. Accordingly the patient was placed on the operating table. While the preliminary preparations were being made, namely the assortment of the instruments, washing the hands of those who were to participate in the operation, etc., the patient was suddenly seized with fright, refused to be operated on and at once left the hospital. Since then there has been no return of pain in the right hypochondrium. Towards the end of his peregrinations, he observed a slight cloudiness of his urine. At once he conceived the idea of a kidney affection. Again he consulted several internists each of whom made a different diagnosis. It is at that time that I had a good opportunity to see and keep him under observation. It must be mentioned at this juncture that during the entire illness of several years' duration the patient continued uninterruptedly his usual occupation namely that of a railroad conductor. He always slept well and had a voracious appetite.

At the time of the examination there was no doubt in my mind as to the psychogenic origin of all the complaints of the patient. Psychotherapeutic management alone succeeded in removing the last obsessive ideas. He is well at present, but since such disorders are episodic in character, the probabilities are that new hypochondriacal manifestations will eventually make their appearance when confronted with new emotional factors, the nature of which will be discussed below.

CASE IV.—In a girl of seventeen there developed abulic phenomena. If while crossing a street she would notice a loose brick on the ground, she would be seized with fear and a state of extreme anxiety if she could not and would not step over the object, but go around it and continue her gait. When, however she would make an effort to overcome her deficient will power, she would tremble, cry and stop. Being slender and pale and having irregular and scanty menstruation, she was taken first of all to a gynecologist whose diagnosis was anteversion of the uterus and that the latter was the direct cause of her psychoneurosis. He urged an operation. A general surgeon consulted subsequently spoke of uterine adhesions and advised some surgical procedures the nature of which I could not determine. A laparatomy was performed with the result of a decided intensification of her psychic condition as well as of her menstrual difficulties.

Examples, such as the few related, could be multiplied, but they are sufficient to demonstrate that

besides a physical there is also a psychological approach which after all may be the most important if not the only method in managing psychoneuroses. An organic or structural lesion can no more be viewed as the sole basis of functional psychic disorders. In order to know how to manage these peculiar phenomena, let us briefly consider their nature and their meaning.

The behavior of every individual is the result of an interrelation of several elements, namely, emotional instinctive tendencies, such as fear, anger, selfassertion, attachment, also the environmental conditions. The instinctive tendencies will have a different coloring in different persons according to inherited qualifications, that is to say a highly or less sensitive person will manifest his or her emotional elements in different ways. The constant interaction between these instinctive emotions and environmental objects or occurrences produces complex psychological states or complexes. We live therefore in the midst of daily or hourly conflicts between the inherent and exterior elements. Complexes are being created continually. When they are recognized by the individual self, the conscious ego is able to overcome them and the normal state is maintained and not disturbed. Many complexes, however, are not recognized, and since all complexes are different from each other and have a different aim and purpose, antagonism of one to another is constantly being created. As they are not recognized, as the conscious ego has no control over them, they may remain with us an indefinite time and are apt to create functional nervous disorders or psychoneuroses. In fixed ideas, obsessions, fears, states of anxiety, abulias, etc., in all such cases as we have seen from the histories of the few patients cited above, the physical symptoms alone emerge, such as pain in the hypochondrium simulating appendicitis, pain in the cardiac or pulmonary region simulating a disease of the heart or lung, etc., but the emotion associated with the fixed ideas remains, and as long as the latter is unaltered or not removed, the physical manifestation remains and the patient will continue being unhappy and a sufferer.

The various physical manifestations of psychoneuroses may be relieved and the individual may find with an effort on his part a certain skill in adapting himself to his environment and become more or less contented for the time being. But such a situation is not a cure, because the essential element in the conflict of various complexes has not been attacked, namely the emotional instinctive factor, which plays the most important rôle in the psychoneurosis.

It is not only the adaptation to the environment, but also and more emphatically the adaptation to oneself that is important. Otherwise speaking, a psychoneurosis can be removed only when the sufferer is shown how to unravel and lay bare the elements of the complexes which are in constant conflict so as to fit him to face himself. Attempts to remove physical discomfort will not remove the emotional elements which have created the psychic discomfort and which the patient will continue carrying with him indefinitely. The inability of understanding this essential principle and the want of desire to consider a psychological end in human suffering besides a purely biological end—are the cause of failure of treatment. Therein lies the reason of the fact that frequently the cause of psychoneurotic disorders is sought elsewhere: in the uterus, ovaries, in the genitalia in general. Next in order is the digestive apparatus that is not infrequently incriminated. Dilatation of the stomach, gastroptosis, enteroptosis, nephroptosis, cholecystitis—are all conditions that are thought of and major operations are often performed. Not only is there total therapeutic failure as far as the patient's complaints are concerned, but undesirable local and general consequences may arise which will render the operated individual organically unfit in addition to his psychic unhappiness. As one of many examples of this particular contention I may call attention to the damage produced by castration in women. In 1914 in a paper read before the American Medical Association (Vol. LXVIII, p. 1345) the medical histories of 112 women who underwent complete or partial removal of the uterus or ovaries or of both, were presented and were extensively discussd from the broadest viewpoints by internists, general surgeons, gynecologists and neurologists. It was shown that the preexisting nervous and psychic phenomena, for which the operations were undertaken, became aggravated in the weeks and the months following the operations. The obsessions and other psychoneuroses from which several women suffered prior to the oophorectomies became since then more persistent and covered a larger field of morbid ideas than heretofore. Those who suffered from the hysterical paroxysms began to have them in a more accentuated form and more frequently. Former hypochondriacal and anxiety states became deeper. All such cases were referred to the gynecologists with indiscriminate assurances that their vague nervous manifestations were exclusively due to indefinite gynecological conditions. Of course the operations were uniformly successful, but the victims' existences were rendered most unfortunate and distressing. It was evident that partial or complete hysterooophorectomies disturbed the well established physiological effect of ovarian tissue on the economy or perhaps disturbed the intimate relationship between various ductless glands, which as we have some reasons to believe, exists. At all events, in addition to the preexisting psychic phenomena additional disturbances were thus created.

The foregoing observations are sufficiently illustrative to contend that the real cause of psychoneurotic phenomena does not lie in accidental occurrences, such as traumatism, fatigue or local diseases. These factors react on us all daily, hourly, and do not produce disorders of a permanent nature. A psychoneurotic individual on the contrary reacts differently because of his special makeup, of his special mental characteristics. The latter render him highly suggestible, highly sensitive and highly emotional. While they do not present new phenomena which are not observed in normal individuals, their reactions, however, to all kind of stimuli are expressed in a greater intensity and are reproduced with a greater facility and branch out in a most unexpected manner. The complexes which were described above and which we considered as the result of conflicts between the instinctive emotional elements and the environmental occurrences are not easily recognized and they are not properly interpreted when recognized by

psychoneurotic personalities because of their peculiar characteristics. The complexes which arise in them are more numerous, more antagonistic to each other because of the greater intensity of each emotional element which enters into the formation of the complexes. The environmental factors which also form a part of the complexes equally give a different sensorial impression in the psychoneurotics and consequently the mental representation in the latter will be different from that of normal persons.

The methods employed in the management of psychoneuroses are several. The object of the present thesis is not the discussion of methods or procedures in bringing to the surface the modus operandi of the complexes which are the basis of psychoneurotic phenomena. My sole purpose is to call attention to the fact that all these abnormal manifestations are too psychic in character, that the functional disorders of which the victims complain are too much dependent upon special mental attitudes to be attributed exclusively to organic disorders of tissues and organs. Psychoneurotics are psychopathic individuals. They occupy a place between insane and normal. Their number is legion and their multiple manifestations present infinite varieties and subvarieties. The latter are intermingled and mixed with human suffering in all its forms and degrees, medical as well as surgical.

In dealing with human life it behooves us medical men to approach its phenomena not only from a purely biological but also from a psychological standpoint. The former has for object the adaptation of the individual to his environment. The latter is to have him adapted to himself. It is only after the latter task has been successfully accomplished the individual will be fit to face his environment. No removal of tissues or organs, no artificial correction of disturbances, however accurately or skillfully they may be done, will succeed in making a psychoneurotic discard his fixed ideas, his hypochondriasis, his abulias, his fears or his obsessions, if he or she is not taught properly how to restore peace amidst the bewildering complexes.

1812 Spruce Street.

Postoperative Neuroses*

PHILIP R. LTHRMAN, M.D.
New York

The term postoperative neuroses though a frequent clinical designation finds little discussion in medical literature. When case histories of this alleged illness are reviewed, one is impressed by the looseness with which this term is used. There seems to be no uniformity of opinion on what constitutes a postoperative neurosis. Consequently many types of psychoneuroses, if found subsequent to a surgical operation, are placed in this group. The validity of such diagnoses may be questioned for the existence of this diagnostic category is not yet established.

What suggests itself as a working basis is the limitation of the term to those neuroses which begin soon after the performance of an operation, and the subsequent illness should be not only superimposed but psychologically related to the operation. Then a careful study of the symptomatology may reveal either a difference from or similarity with the usual psychoneuroses, and the rôle of the operation evaluated as the provocative agent in the etiological moment.

A similar field of inquiry may be taken for comparison, i. e., the war neuroses. Here the direct causative factor of the war on the illness is not debatable. The mechanisms uncovered were not only those involving the object libido but also the ego libido. The significance of the trauma was chiefly in its element of surprise, in fright. In fact it is generally conceded that an injury or wound sustained at the time of the shock tended to prevent the occurrence of neurosis. Preoccupation with the traumatic incident is rare, and Freud regards it as significant that the traumatic incident is actively crowded out of consciousness; the sufferer strives to forget what has occurred. Only in dream life is the situation of the trauma lived over again. The dream continually takes the patient back to the occurrence of the disaster from which he awakens in renewed terror. This attitude of the traumatized sick individual is in contrast to the attitude which is usual in persons who have gone through a harassing experience but who have not shown any neurotic illness subsequently. The latter do not miss an opportunity to relate their experiences, and often exaggerate the importance of their own participation. In this regard they resemble the postoperative patient without neurosis who dramatizes all events relative to his operation, such as, the greatness of his surgeon, the duration of the operation and the miraculous performance.

Though superficially analogous, it becomes evident on closer examination that there is a marked difference in the circumstances and effects of the operation and the trauma. Though there is at the time of operation an element of fear, it is not that of fright. The element of surprise is lacking. A wound is always produced. The operation is recalled as having saved one's life, whereas the trauma is remembered as the near escape from death. The operation dream is an infrequent occurrence and is not one of anxiety. However, the behavior of the traumatized healthy person and the usual postoperative patient may have a greater significance than is ordinarily accorded to it. Certainly one does not find such dramatizations among patients in whom there have developed neuroses subsequent to operation. This continual reference to the operation and the praise of the surgeon would seem to serve an economic need in the distribution of the libido, by affording an outlet of organ libido which strives for a place

*Read at the New York Academy of Medicine, Section of Neurology and Psychiatry, March 13, 1924.

of recognition in consciousness. It thereby prevents the damming of local libido of an organ, the erotogenic zone of which is stimulated by the surgical procedure.

The practical implication of these theoretical considerations is of great importance once we accept the psychoanalytical conception of the socalled functional psychoses (dementia precox, paranoia, manic depressive) as being due to narcisistic fixation.

That the psychoanalytical method may help in the elucidation of this problem seems plausible from the richness in results its application has produced in the entire domain of mental illness. The factors involved by Freud in explanation of the psychoneuroses have been amply corroborated, not only in the mental illness of peace time but as well in the neuroses of war. To be sure the external factors as brought about by war situations varied from peace time conditions in the causation of neuroses, but the essential feature that the illness was the result of unconscious mental conflicts has been demonstrated by MacCurdy, Brill, Jones, Ferenczi and others.

That the current factor, as in the instance of the war, may play the most important part in the immediate causation of the illness cannot be denied. Only in a few instances can the current factor be entirely eliminated as playing a part in the beginning of mental illness. Freud has pointed out that it is not the unconscious conflict alone which produces the illness. Environmental and current difficulties play no small part, though without the unconscious conflict no serious mental affections could be produced. Present day mental hygiene does not neglect the current conflict, though it attempts to attack the faulty unconscious adjustments. Until we are able to evolve the technic for a more rapid approach to the unconscious, all immediate promptings of a neurosis or a psychosis ought to be evaluated and if possible eliminated.

In this study twenty patients, in whom there had developed mental illness subsequent to operation, were carefully examined. Six cases representative of the group will be cited. The operations were performed on nonacute conditions. Among the operations on record were: tonsillectomy, nasal mucus resection, plastic surgery on nose, hemorrhoidectomy, appendectomy and cholecystectomy for chronic pain. In one instance which I will cite in greater detail, the operation was merely the removal of a wart from the thumb of the right hand. The mental illness which followed in each of these cases did not differ in type or course from the generally accepted classification of neuroses and psychoses. That the operation played a rôle in the constellation of the symptoms will be noticed from the following case abstracts.

Case I.—Male patient, twenty-eight years of age, complained of a queer gnawing sensation in the right thumb and hand since the excision of a wart on that hand, two years previously. He appeared anxious, could not be reassured, slept badly, and insisted that some vital nerve was damaged during the operation, or that a needle might have broken and worked its way to his brain and caused his marked nervousness. He realized the senselessness of some of his worries but complained that he was powerless when they possessed him. He soon had to limit his social contact and gave up his work as a mechanic, for he feared that in the presence of people he might have that queer sensation in the right hand which might embarrass him in some way, as in handling a tool, or putting on his coat or in eating. There were no abnormal involuntary movements nor any sign of disturbance in the motor or sensory fields, to warrant this fear of clumsiness. It was clearly a case of anxiety hysteria, and the current provocative agent was the slight operation. Without going into a detailed account of the analysis it was evident that the operation represented the realization of castration and the symptoms were the result of this unconscious phantasy. Of interest was the partial impotency which set in soon after the major symptom in the hand. The right hand was the guilty member in many masturbatory experiences and in assaults on a younger sister when he was six years old. When older he apparently overcame his sense of guilt and remained well until the time of the slight operation. Then the surgeon became the unconscious father against whom the neurosis was directed.

Case II.—Male, thirty years of age. He complained of a feeling of protrusion in the lower abdomen "as if something was coming out." He soon became inaccessible and developed into a typical case of dementia precox. The illness developed soon after an operation for inguinal hernia. Previous to the operation there was no evidence of schizophrenic symptoms. He subjected himself to operation simply because he did not care to wear a truss.

Case III.—Male, twenty-six years of age, Schizophrenic symptoms developed after an operation on a deviated septum. He was under the operation an hour and his first symptom was a feeling that his teeth were falling out. After three weeks this symptom was displaced by queer feelings in his hands. He felt as if his hands were detached from his body, and soon all his limbs were similarly involved. There was no evidence of organic neurological disease to account for his hypochondrical complaints, and soon there developed ideas of reference with the surgeon in the central theme. Again the interpretation points to the castration phantasy, involving the unconscious image of the father.

Case IV.—Male, twenty-four years of age. His operation was the correction of a deformity of the right hand due to an old fracture. While in the hospital he began to suffer from typical attacks of anxiety hysteria. He at first feared that he would never be able to use his arm, and this was followed by fears of falling, that he would urinate in public places and that he would lose control of his bowels. Analysis revealed the typical unconscious strivings as found in such cases, and the role of the operation in the initial production of the symptoms.

Cases V and VI.—Plastic surgery on the nose was responsible for producing psychoses in two patients who were brought to the Psychiatric Clinic of the New York Post-Graduate Hospital. In a girl of nineteen, soon after she had her nose deformity corrected, there developed delusions of reference relative to her new acquisition of beauty. Everyone was in love with her, every man was seeking her sexually, and she would spend hours before the mirror. She finally became uncontrollable and had to be committed to a sanitarium. The other patient was

a young man, twenty-seven years old, who soon after an operation for a crooked nose conceived the idea that his looks were forever marred by the surgeon who operated on him and who brought him to our clinic. He spent hours at the mirror, neglected his work became asocial and finally threatened violence to the surgeon whom he blamed for ruining his life. All these ideas developed in spite of the reassurance by his family and friends that the operation was successful. Months later he showed evidence of the same trend in milder form but had other symptoms of dementia precox.

That persons should seek plastic operations on the nose is in itself evidence of marked selflove (narcisism). The individual with narcisistic fixation is potentially in danger of a psychosis when his narcisism is injured.

It has been pointed out by Freud that mental illness may have its start in an auxiliary physical illness. In his patient, Lucy R., there developed hallucinations of smell with an accompanying depression while being afflicted with purulent rhinitis. Similarly, Ferenczi has called attention to the occurrence of a tic, which he regards as a narcisistic neurosis, on the site of local irritation. Other observers have pointed out the serious effects of orificial surgery when patients have presented schizophrenic symptoms after amputations of the clitoris, (Meagher). Actual injury to the penis has been known to produce the same syndrome. It is not unlikely that a trauma sustained by the symbolic representations of the sexual organs will provoke mental illness.

CONCLUSIONS

The psychoses or neuroses following operations are not clinically different from the known categories.

The operation may play a rôle as the provocative agent in that individual who is predisposed to mental illness by the castration complex or by narcisistic fixation. In such persons, surgical procedures, not absolutely necessary to save life, are to be avoided.

120 RIVERSIDE DRIVE.

The Psychiatric Clinic and the General Hospital*

C. P. OBERNDORF, M.D.

New York

The recognition of insanity as a corollary of the baffling situation in social adaptation and organization is a twentieth century achievement. With this knowledge gained through the study of insanity has come the practical application of social problems. As the result of this new point of view there has developed a significant change in the relationship of the hospital for the insane to the community in general. The hospital is emerging from its previous isolation, pacifying those who are outside but narcotizing alike the physician and patient within its walls. It has extended its communications with the outside world through an increase in number and activity of its extramural consulting staff, through the elaboration of a social service system for the aid and supervision of paroled patients and through the inauguration of psychiatric clinics administered by the hospital staff in the larger cities of the territory served. The New York State Hospital system sponsors about sixty such clinics. These are held with varying frequency, sometimes in small towns. From the community, principally through social, educational, corrective and legal agencies, there has arisen an earnest attention to conditions resulting from conduct disorders bordering on insanity. These civic organizations appeal to the psychiatrist—to the hospital for the insane which is back of him—for enlightenment, guidance and paradoxically enough, inspiration.

In this convergence of attention on psychiatric investigation, so intrinsically an adjunct of medical progress, the general hospital and the general practitioner have remained indifferent and disinterested. In many instances the ignorance of the physician stands out in striking contrast to the more advanced conception of the intelligent layman in regard to the vast problem of mental disease.

Similarly the general hospital has failed to appreciate the significant power it has to render social service to the community in connection with mental disease. This has been due partially because of the inadequate instruction in psychiatry which up to recent times was offered in the curricula of the best medical schools. So the average physician's concept of insanity and insane people did not vary essentially from the prevalent conceptions of awe, loathing or hopeless pity entertained by the public. However, the community, the hospital for the insane and the general hospital itself have much to gain through the operation of psychiatric clinics as an integral part of the hospital scheme.

The greatest benefit from the arrangement undoubtedly accrues to the mental clinic, for in a large proportion of cases the psychiatrist will detect physical conditions which may have a bearing upon the psychical manifestations for which the patient is referred, notably cardiac and gastrointestinal disorders and visual and hearing defects. Moreover, clinical laboratory cooperation often forms a determining factor in establishing a diagnosis, especially where syphilis is suspected. The recently increased attention to the glands of internal secretion as possible influences in producing conduct disorders, has made the x ray laboratory and metabolic studies almost indispensable. The mental clinic located in the same building or adjacent to a general hospital dispensary enjoys the benefit of expert assistance from other specialties and an immediate rapport with the physicians making the tests.

The patient derives an immeasurable amount of assurance in a diminution of the stigma which still

*Read before the Section on Neurology and Psychiatry, New York Academy of Medicine, December 19, 1924.

unfortunately cling like a pall about mental diseases, for when he visits a clinic located in the same building for other medical specialties he feels himself in no way distinguishable from others suffering from diseases conventionally accepted by society as an inevitable part of life's scheme. This seemingly slight circumstance tends to mitigate the feeling entertained by so many sensitive, mentally afflicted people that their trouble must be regarded as a disgrace to themselves or is so considered by their families. The latter is far too often true.

The social service worker, whose aid has become so extremely valuable in this field, finds that her delicate task of inducing psychopathic patients and their families to coöperate in treatment, is tremendously facilitated if she can refer the patient unconditionally to a general hospital which has gained the confidence and respect of the community, rather than an independently organized psychopathic hospital. The latter is so closely associated in the mind of the layman with the more violent and disagreeably spectacular forms of insanity, which are recorded daily in the press, that it is often regarded with suspicion, dread and repugnance. Social service workers who have had experience with both types of psychiatric clinics, that is, the independent and the affiliated, will corroborate this statement.

The objection raised that the presence of neurotic and psychotic patients in a general dispensary building would prove disturbing if not alarming to other patients has proved footless. Even with twenty-five patients in attendance, twenty per cent. of whom are considered psychotic, the dispensary attendants have found no greater difficulty in handling them than those visiting in any other department.

A plea is made occasionally for independently operated psychological or psychiatric clinics for the socalled socially maladjusted patients of the school age—the popularly termed problem cases, showing conduct delinquencies of various types. The advocates of these clinics assert—with some justification—that the social point of view is obscured in the handling of these cases by the restricting precision of scientific training of the modern doctor and the rigidity of hospital organization. However, I feel that both these disadvantages, and neither is irremediable, is more than counterbalanced by the contributions which scientific medicine can bring to bear upon the solution of perplexing mental problems. Often, as in the case of psychic symptoms dependent on a brain tumor, anatomical diagnosis is the only solution. On the other hand, the very presence in an outpatient department of a clinic where the social point of view should unswervingly predominate, reflexly, often remotely tends to alter the all too rigid and impersonal attitude of surgeons and even physicians. They sometimes regard their function to be exclusively the alleviation of an isolated pathological condition, quite apart from—possibly not even giving a thought to—the many-sided social attachments and aims existing in every human being, often affecting his reaction to and recovery from such a distinctly physical injury as a Pott's fracture.

Some years ago with the reorganization of the Neurological Department at Mt. Sinai Hospital, a clinic in mental health was established in the outpatient department, the chief of which was an adjunct neurologist in the hospital, thus bringing the work of mental hygiene into closer contact with the neurological division and the hospital in general. To my knowledge this is the first instance of the creation of a mental hygiene clinic in direct connection with a private general hospital in New York city. It was furthermore intended that patients requiring further tests or prolonged observation should be admitted to the neurological service of the hospital provided that their actions or conversation were not of such a nature as to disturb other patients.

The clinic is strictly a refer clinic, that is, no patient is admitted without an examination previously by physicians in other departments of the dispensary or outside physicians. Social service workers are welcome to bring their socalled problem cases directly to the clinic, but these patients sometimes have also had thorough physical examinations.

With a view to determining more accurately the type of persons using the clinic and the scope of the service which the clinic returns to the community, we reconsidered the first hundred consecutive cases[1] admitted in 1923.

The statistics concerning occupation, sex, race and religion afford little of general interest as they are dependent upon local conditions and the hour of the clinic. However, a few observations seem worthy of record. The first is that an eager daily attendance has demonstrated irrefutably the demand for psychiatric treatment by a group of patients who come voluntarily and present conditions requiring a specialized approach and subsequent handling. In many of them, especially adolescents, prophylactic measures appear to have been of considerable influence in forestalling more serious mental involvments, such as the progression to fully developed dementia precox states, and even the prevention of manic depressive attacks. A surprisingly large number of patients come not from the financially poorest strata of society but from the comfortably situated, by which term we mean persons connected with families, the combined income of which is sufficient to furnish food, clothing and housing of a quality necessary for health, without the assistance of charitable agencies. However, it is precisely in this type of family that the entire domestic equilibrium topples when mental disease seriously incapacitates or claims one of the productive members, whether it be a wage earner outside or the housewife upon whose domestic duties the home depends for its survival.

The sources through which the hundred cases were recruited, are divided almost equally between medical and social organizations, emphasizing the double function of the psychiatrical clinic previously mentioned. Over forty per cent. came for more specialized treatment from the various departments, both in and outpatient, of the hospital. Eight per cent. were sent directly by their private physicians. Organized social agencies were responsible for over forty per cent. and the value of our cooperation was apparently sufficiently great to induce one of these to engage a psychiatrist to handle its cases,

[1] I am deeply indebted for the assistance of Dr. D. D. Schonfeld and Miss Ida Segal, in making this study, which was undertaken primarily in order to furnish data for Dr. Frederick Brush of the Burke Foundation at White Plains, New York, where the establishment of a ward to provide for persons suffering from minor mental disorders is contemplated.

largely juvenile conduct disorders, at its own quarters. As none of the cases were referred by the courts or complicated by criminal charges, we were able to operate with greater latitude than where legal requirements must be considered.

The various hospital services increasingly seek psychological advice in regard to some of their physically afflicted patients, for the most part cases of conversion neuroses of gastrointestinal and cardiac types at times complicated by compensation considerations, and hyperthyroidism. Even the recalcitrant surgeons occasionally call for psychological investigations in connection with cases of abdominal pain or persistent vomiting to be sure more often after than before operation.

DIAGNOSIS OF ONE HUNDRED PSYCHIATRIC CASES

Outpatient Department

Psychoses

In the diagnostic classification of cases, so much depends upon the training and point of view of the examining physician, that statistics do not convey an absolute indication of the nature of the cases handled. The gradual merging of neuroses into dementia precox on the one hand, and the depressions of the manic depressive group on the other, allows considerable latitude in the grouping. In general our tendency has been to classify these conditions as neuroses rather than psychoses. In diagnosis of the psychoses and constitutional defects (fifty-one per cent. of our cases) we have followed the concepts embodied in the nomenclature of the New York State Hospital Commission, and in the neuroses used the Freudian distinctions in our subgrouping, although nearly all socalled specific neuroses of Freud's classification include some of the features supposedly characteristic of one or another type. However, the term anxiety neurosis is used to indicate a situation where the outsanding factor is an unquestioned sexual abnormality still existent and operative in the life of the patient. Conversion hysteria indicates the unconscious symbolic expression of an emotional reaction by means of physical manifestations, such as the expression of disgust by vomiting or the desire for compensation by functional paralysis. Under neurasthenia are included those cases where the emotional disorder is accompanied by some evident toxemia, excessive masturbation or actual physical disease, which was held to be responsible for the fatigue and irritability. Compulsion neuroses indicate those cases where obsessive ideas alternate with uncontrollable doubt. Mental defectives, below the grade of constitutionally intellectual inferiors, did not apply for treatment probably because of the state provision for this group in New York.

The results of treatment in neurotic and psychotic patients is especially difficult to gauge and we should be wary of the word cure, which so often conveys little more than the whimsical personal conception of the physician reporting the case. We prefer to disregard the terms improved or cured in favor of emphasis upon the fact that the point of approach in all the functional cases has been an attempt to ascertain the subjective attitude of the patient toward his illness and problems, and to refrain from imposing upon him, as far as possible, the objective interpretation of the examining physician. At times when in the pressure of work we are compelled to assume the directing rôle, we are often in a position to advise (more pertinently and effectively, we believe) on the basis of analytic interpretations.

In a few cases of conversion hysteria and compulsion neurosis, a brief psychoanalysis, following the technic of Freud, and devoting over half an hour three times a week to the patient, has been undertaken with satisfactory results. However, as a rule we have not hesitated to use eclectically every means at our disposal indicated by clinical expediency in attempting to readjust the patient to his life's work and situations, namely, advice, persuasion, reeducation on the basis of psychoanalytical knowledge, special schools, visiting nurses to the home, recreation under the personal direction of the social service worker, rest in the country away from environmental annoyances and occupational therapy. The results, brilliant in some instances, are counterbalanced by discouraging developments in others. Approximately half of the patients attempted to cooperate to the fullest extent with the instructions of the physicians and social service workers.

The outpatient occupational therapy which is in charge of a paid worker with volunteer assistants, but housed in inadequate quarters, has proved a desirable adjunct to our reeducational and analytic procedures in the neuroses. In the psychoses, especially in the dementia precox cases and mild depressions, its primary value in arousing the interest of the patient hardly exceeds its secondary value of freeing the home for a number of hours each day from the care and burden of these patients. It has proved of some diagnostic value as a practical test, in that the manner of application to their tasks and attitude toward their coworkers, has revealed characteristics of the patients, sometimes not given a full valuation in the history or the oral examination. Many of the psychoneurotics find occupation a means of temporary distraction from their compulsive thinking and welcome the association with other persons inasmuch as their mental disability has frequently incapacitated them from initiating normal contacts in their own environment. It soon became evident that unless the patient regard the work seriously as an adjunct of his treatment, he would refuse

to cooperate, and that to the average dispensary patient, the presence of a doctor signified treatment. For that reason the moral support of frequent medical consultations with the therapist in charge in the presence of the patient, is indispensable. While the recreational and therapeutic aims are never slighted, we find it of advantage to pay the patients one third of the sale receipts of their work.

The activity of the clinic for three years has shown vast possibilities for extension of its scope which only the limitations of medically trained assistants and space has halted. These potentialities may be indicated in the testing of supposedly normal children, the psychological investigations of the emotional problems of the slightly deviating high school girl and boy, the behavior problems in the preschool age and the intensive superintendence of mildly psychotic patients residing at their own homes. Our experience has also emphasized the long felt need of a hospital or a ward for the temporary reception of borderline cases, who are not sufficiently ill to warrant even their voluntary residence at a state hospital, yet whose conduct is intolerable and misunderstood at home or whose environmental conditions are such as to greatly jeopardize the chances of recovery.

The Treatment of Peripheral Nerve Paralysis With Diathermy*

A. LUX, M.D.
New York

Inasmuch as electrotherapeutics is not generally recognized as a factor in therapeutics, paralysis and electricity are in the minds of most physicians inseparable terms. From what I have seen, I might even say that this latter form of treatment is more often used by the profession than is justified in most cases. French and German authors have not been idle in setting forth various theories as to how and why electricity is the proper treatment for paralysis.

The fact that there are numerous theories points to the correctness of my teacher, Bergonie's frequent statement that little is known concerning its specific action. But even if we cannot as yet offer a generally accepted theory, it still remains an absolute fact that the irritability of muscles is greatly increased after the application of a constant current. This has been observed by Babinski. This increase of irritability can be definitely proved. A patient with a paralysis of the musculospiral nerve secondary to pressure will show, after the application of a constant galvanic current, an increased irritability of this nerve and the muscles supplied by it. The value of this observation has been greatly misunderstood. It is absolutely erroneous to expect a curative result upon a paralyzed nerve by means of electricity. Experiments made on rabbits and observations of cases of all types have led us to the following conclusion: We do not believe that the electric current has a specific curative influence upon the paralyzed nerve. We are neverthless convinced that the constant current greatly increases the irritability of muscles and that according to a more recent theory the interrupted current in both forms, galvanic and faradic, prevents an atrophy of nerves.

I have for a long time known these facts and, somewhat discouraged by the limited usefulness of electricity, some years ago tried to use diathermy in the treatment of nerve paralysis.

Diathermy is a high frequency current of high voltage and low amperage, which produces a resistant heat in the body without any electric sensation. It makes it possible as a result to administer heat upon deep organs and thereby produce hyperemia in any deep seated part of the body.

Some years ago a girl of twenty was referred to me with a contusion of the arm, with paralysis of the musculospiral nerve by trauma. I decided to treat this contusion with diathermy and strangely enough the paralysis subsided long before the ecchymosis, swelling, pain, and other features disappeared. I then treated a series of cases of nerve paralysis with a combination of diathermy followed by electric stimulation with the idea of hastening the process of nerve recovery by diathermy and also to take advantage of the influence of the interrupted current as pointed out before. The difference in the outcome of cases treated by this combined method compared with cases treated by electricity alone has been striking.

I unfortunately presented my ideas much too early to a small group of electrotherapeutists. The findings of most of them did not accord with my ideas. It was by accident that I discovered the error made by these physicians. One of the patients, with facial palsy, was severely burned by one of these experimenting physicians. In checking up this case I soon discovered that the limit of diathermy had been administered with the false conception that more heat meant more hyperemia.

The enormously sensitive mechanism of heat regulations of the body had not been considered by these physicians. It is well recognized, however, that the organism has a tendency to maintain an equal amount of heat all over the body within a certain physiological limit. It is evident that if a certain part is overheated, that this surplus amount of heat is carried away by means of the perspiration and the more rapid action of circulation from this particular part in order to equalize the body temperature. This action naturally renders the effect of diathermy also almost nil. Therefore, let me state quite definitely, that the maximum of diathermical effect does not necessarily mean the optimum of result.

In a long series of experiments on animals, I have carefully studied the effect of diathermy upon every type of tissue. Based on these findings I have postu-

*Read before the New York Neurological Society, February 3, 1925.
[1]Patient demonstrated before the New York Neurological Society in the Academy of Medicine, February 3, 1925.

lated the various methods in applying the current to different parts of the body.

In the course of this paper, I cannot go into all these details which are after all only technical questions of the treatment and likely to be of minor interest. I wish, however, to point out the fact that the results are absolutely dependent upon the correct application and thorough understanding of the indications. In the course of the last three years I have treated over one hundred cases of nerve paralysis, peripheral in origin, with excellent results.

Due to the fact that electrotherapy is still in its infancy, cases are mostly referred to us as a last resort and after all other forms of treatment usually have been attempted. And as a result, *ultimo ratio* an electrotherapist is given a rather unfair chance.

In September, 1924, a young gentleman was referred to me with the following history: Sixteen years ago a mastoid operation was performed on the patient. The facial nerve was injured in the course of the operation, which resulted in a complete peripheral facial paralysis of the left side. Electricity in all forms was tried in various institutions without any result and when the patient was examined at the Montefiore Hospital, the status was as follows:

"Face is drawn to the left side, no nasolabial folds visible on paralyzed side. By attempt to whistle or show teeth, typical picture of facial paralysis. Patient cannot close lid at all and the cornea shows signs of superficial inflammation due to exposure. Sensory of skin normal. Patient states that his face has been the same for the last sixteen years. The electrical reaction reveals partial reaction of degeneration of left facial nerve." Our impression of this case was typical facial palsy due to injury.

Diathermy was applied according to the usual routine. After five treatments patient reported that he felt as though his face was more pliable. After ten treatments the patient made the first attempt to close his eyes spontaneously.

Status made after twenty-four treatments shows: "Face appears equal on both sides. Nasolabial fold is distinct on both sides. Attempt to whistle. Showing teeth shows no abnormality. Patient closes eyelid spontaneously. The electrical reaction of facial nerve reveals no difference as compared to the other side of the face."

The question now arises what explanation can be offered for such results in the treatment of nerve paralysis with diathermy especially in the case presented. It is rather unusual for us to obtain results after sixteen years' duration. Possibly there was a scar left on the facial nerve of the patient due to the injury he received. By localizing the site of this scar we were able to concentrate the entire diathermy current on this very spot and propagated the absorption of scar tissue. The hyperemia set in the entire course of the facial nerve has undoubtedly helped the regeneration of the nerve fibres which have been atrophied by the years of disuse.

As you will notice, I am constantly referring to the effect of hyperemia caused by the diathermy current and you will undoubtedly ask why should not baking or other forms of treatment, which also produce hyperemia, be of the same value. The fact is that the hyperemia produced by diathermy is entirely different from hyperemia caused by other forms of treatment. Baking and similar methods primarily warm the skin or mucous membranes and attempt to penetrate the deep organ subject to treatment. The current of diathermy produces heat directly in the organ itself, no matter how deep seated it might be. Not only this penetrating effect of diathermy is what makes it so effective, but another important factor should be kept in mind. The warmth produced by diathermy is originated by a free energy which is introduced into the body by means of electricity. The warmth produced by the baking on the other hand is heat obtained by the energy of the organism itself and not as in the case of diathermy by an energy which is brought into the body. The principle of baking is to encourage the chemical interchange by increasing the local metabolism through the reaction set forth by the baking of the skin. In other words, the hyperemia of the organ to be treated is due to the biological reaction of the body upon the sensation of heat.

As you will see, there is a fundamental difference between the two methods. While diathermy brings a surplus of energy into the diseased tissues, baking and all other heretofore known forms of treatment cause an increased use of the body's own energy.

Diathermy Treatment of Paralysis from Epidemic Poliomyelitis.—Hugo Picard (*Monatsschrift für Kinderheilkunde,* June, 1924) states that the diathermy treatment of epidemic poliomyelitis if instituted immediately after the cessation of the febrile stage of the early part of the disease, resulted partly in complete cures and partly in marked improvement. Inasmuch as most of the symptoms of the paralysis are due to the pressure of the inflammatory edema upon the nervous muscle elements, a reduction of the edema and with it the cessation of the pressure is obtained through the diathermy. In addition, a destruction of the bacterial agent is brought about as a result of the high temperature induced. For localized paralyses (arm or leg) a transverse penetration of heat of the corresponding spinal segment and for complete paraplegias of both extremities the longitudinal, or possibly, a combined application is recommended. In addition, a peripheral diathermy treatment may be given to paralyzed extremities with marked hypothermia. The strength of the current for the transverse application should be 1.1 to 1.4 amperes and for the longitudinal application 0.9 to 1.1 amperes. Great care must be taken to avoid injuries. The duration of treatment is two months, daily at first and later every second day. Every application should last about fifteen minutes. Massage and active motion and the avoidance of deformities are also necessary.

Treatment of Epidemic Encephalitis.—Edwin Matthew (*Lancet,* June 7, 1924) obtained some very good results with the use of intramuscular injections of a twenty-five per cent. solution of magnesium sulphate in doses of four c. c., especially in cases of painful myoclonic contractions and marked choreoathetotic movements. The second dose is given twelve hours after the first, and the third and succeeding doses, if necessary, are given at intervals of twenty-four hours.

Historical Medicine

Modern Medical Ethics and Those of Plato

JONATHAN WRIGHT, M.D.

Pleasantville, N. Y.

In the *Charmides* when Socrates starts off with the idea that even a bad man may unwittingly do that which is good and as it naturally follows that a man unaware or unconcerned as to the result of evil may do either, the discussion takes the channel Socrates sets for it. Incidentally almost we pick up a whimsical remark of his that leads us into a labyrinth from which we do not always escape in medical ethics today. A man may not always be right in supposing it is of advantage to him to be cured of disease. Even the doctor is sometimes mistaken.

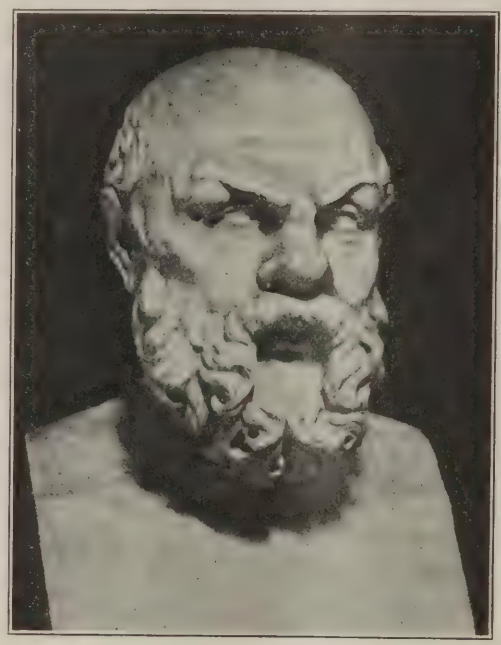
The question of right and wrong has very many facets. A doctor may be conferring by his ministrations at once a benefit on the patient, on the community, on the nation. On the other hand the interests of the individual and the group may clash. As practitioners we are apt to think our duty is primarily to our patient, but as health officers or army officers this is not always so plain. We may see the conflicting interests of both the man and the group or of neither. "A doctor may restore his patient to health without knowing whether it is good for him or not," Socrates says, and we see the complexities of ethics, before he gets through. Is health good for a man? What possibilities of shocking the medical profession with antitheses! Cure him of his wound and the sergeant will place the man on the firing line again where he certainly will be killed this time. Is that good for him? Who knows? Perhaps, but opinions may differ. The man himself might admit it was not good for him to be cured of his former wound. He would be pretty sure to think so. We all know what malingering is and the doctor's duty to his patient may well assume a dubious hue. He may need shelter even if not sick.

Is ethics something in the way of rules which is to make us mindful of the interests of the state or of the art of medicine? Does neither ever conflict with the interests of the patient? Again do we owe nothing to the spirit of Truth itself? to our own self respect? Ethics is indeed a thorny problem. Plato in the *Republic* approaches it in this way (No. 459): "When patients do not require medicines but have only to be put under a regimen the inferior sort of a practitioner is deemed to be good enough," the sanitarium director who, in Plato's understanding of the matter, follows the orders of the practitioners who are his patrons, if we may modernize the thought thus. It simplifies the matter greatly for both, for the practitioner and for the sanitarium director or for the specialist to have but *one* conflicting interest, financial, a splitting of fees. When, however, we put this behind us and consider alone the interest of the patient and the line of treatment we enter into the difficulties of practitioner and patient which Socrates faces. As to the regimen the house doctor does not have to lie and can be a quite inferior sort of person, "but when medicine has to be given then the doctor should be more of a man . . . a considerable dose of falsehood is necessary for the good" of the patient. As to the spirit of Truth itself, in the previous essay we have seen how deceit was to be used in furthering the interests of the state in the way of breeding citizens for the *Republic* and we may question perhaps the devotion of Plato to the application of the principle of abstract Truth. In this passage with which we are here concerned and in many others running immediately into the discourse of the dialogues we perceive how low intellectually Plato rated medical men. What business had they in the discussion of abstract ideas of the good and the true and the beautiful? They were affiliated with an order of thought which removed them from the higher ranks of intellectual life. They devoted their lives to the observations of the nature of man and its relation to the nature of the universe. How could they have any part in the realities of metaphysics continually immersed as they were in chimeras?

I am not here going to stray into a discussion of Plato's ideas as to the realities. It is not for me to say how much doctors lie to their patients. I have done a little of it in my day. They never do so so earnestly and foolishly as when they tell their fellow practitioners they never do. There seems to me there is no question the practice is a common one. Of course collated with and included in it as I use this ugly word is much else than the unequivocal lie. I use it to save time. I refer not so much to literal lying as to its cognate phenomena. How often it is necessary and how much it is necessary varies very largely no doubt, but it is this aspect of it especially which is such an evil for the practitioner himself. It is a bad habit. It degrades a man's inmost soul—no more in the form of a plump lie than in whipping the devil around the stump. The latter degrades a man's intellectual nature too. There is no such hopeless case intellectually as the man who is in the habit of lying to himself. Plato thinks it is not worth while, apparently, to bother about the doctor's spiritual nature. Plato was an aristocrat not only socially and politically, but intellectually, and he saw no reason why a physician, a lower caste man, should not sacrifice his moral nature on the altar of the patient's supposed welfare, even his peace of mind. I take it this is the shade of difference we must see between the ancient and the modern standard, whatever the practice may be. I am sure Plato would have put this argument in Socrates' mouth if he had thought it worth while to waste on a calling of inferior dignity the moral values he reserved for the higher evolved spheres in which his own intellectual and moral nature moved. The difference in the standpoint arises then apparently from a social evolution which allows a doctor the expensive luxury,

theoretically defensible, however rarely practised, of always telling the modern patient the truth.

There are many aspects to this question. I am not going to consider those which urge the valuable therapeutical effect of the hokus-pokus of the vulgar charlatan or his more subtle relative. It is continually intruding itself on our attention. But it troubles the conscience of the man of high respect for his own integrity to think he is violating the interests of the patient, which he has sworn to guard, by keeping his own selfrespect intact. There is a history back of our own ethical troubles, back even of Plato. Suspicion still lurks behind the practitioner of medicine. Primitive man made the life of the medical man a perilous one. In the courts of Augustus and Tiberius, in those of the Borgias and the other bad popes, in every place where wealth and power were sought and schemed for under the old dispensation, the physician and the poisoner have frequently been thought of as living under the same cloak. That belief, if not the literal fact, is what colors history for us with a murky atmosphere. There is free use of the medical art in the way of illustration in the dialogues of Plato, but the reference to the physician is always as to his skill, his knowledge or his ignorance. So far as I have observed there is no word as to his ethical problems. It was the advent of Christ which gave ethical value in itself to a life devoted to the assuaging of human suffering. That did not exist in Plato's day, but we get a hint of the primitive thought. It has stuck like a burr to us long after time was marked by the chronology of Christ's birth, much more than a thousand years after it. "He who can prevent or himself elude a disease is best able to create one."



Term of Socrates. Rome, Villa Albani.

Out of this old situation have grown many tendencies. Much more than from other men the modern public demands of the profession unimpeachable ethics. It has small concern with professional ethics. Honor, uprightness, charity, truthfulness, chastity, it demands of other men too, but it asks the medical man to work with might and main to diminish the need for his services, by rendering which he gets bread for his children. It asks that of no one else. It is a joke, it would seem, too preposterous to be true, but that is the truth of it. The modern doctor should be a State officer, drawing his salary from the State. This is no socialism. It is common sense. In this we touch the heart of the question. There lurks the old suspicion of primitive man in the form. "Am I to be made sick that this man may live, or made to believe I am sick?" Well, when a man lies to his patient and the patient's father to whom he has told the truth sees how smoothly he does it, or how like a snake he glides around the letter of the lie, what does one suppose he thinks? Thankfulness perhaps that the doctor has spared his son the pangs of fear and despair, possibly admiration of how he adds the mind cure to the drug cure, possibly his emotion blinds him for the moment to the doctor's lie, but if he is a man accustomed to judge and weigh men and accustomed to think well of them when the scales stand true at a high notch there comes the thought: "This man knows how to lie." The primitive man questions, "So this man knows how to poison, does he?" There in Plato we find it and since then, in the face of the most serious social and moral handicaps, the profession has won its way to a higher esteem, but there is no escaping the conviction that certain barriers, ethical as well as social and political, must be removed before it attains the highest possible.

In Plato's day the thought of poison was not infrequently to be reckoned with in the prejudice against doctors. Aristotle (Pol. III 16) remarks, "Whenever a sick person suspects his physician has been persuaded by his enemies to be guilty of any foul practise to him in his profession, he then chooses to apply himself rather to a book for his cure. The temptation to poison is no longer thought by our public to be constantly before us. Doubtless we are more particular to tell the truth than the profession in Plato's day. I don't think our code of ethics mentions the impropriety of poisoning our patients. No statute, however, could cover the subtleties of lying. It assumes too many forms. I presume if Plato had been a medical man with experience as a practitioner he would have made his Socrates go to the bottom of the ethics of medical men, but as a matter of fact he just says in effect—of course they lie, and lets it go at that. It has seemed in what has preceded that it behooves us to go deeper into the matter and consider it more closely. Even if we are convinced that under certain circumstances it is to the patient's advantage for us to lie by mind cure or what not, it is perfectly easy to give it a more euphonious denomination. We perceive we are on a slippery path and that apparent self-interest or vanity or something else personal to us, love perhaps, like Moliére's hero, is lurking in our rear and gently urging us on. To this enemy, and he may be legion, we can be sure even our public are much more attentive in observation than ourselves. It is hardly necessary to say more than that, since suspicion treads our path behind our backs, there can not be the slightest doubt that whatever may be the advantage to the patient or how often, our self-interest is eminently, not only to appear but, to be above suspicion. This, thank Heaven, is commonplace enough in our day, but it was not so at all in Plato's day.

In this book of Dupréel's (*La légende Socra-*

tique et les sources de Platon par Eugène Dupréel, Bruxelles, 1922) which has lured me again to Plato I have found little of this analysis which might have occupied the author's thoughts, but I have taken note of his giving credence to a saying of Diogenes Laertius leading up to the discussion as to making the worse appear the better part. Dupréel attributes to Satyrus, the first commentator on Aristotle, the remark that Empedocles not only was a physician but an excellent speaker and had Gorgias Leontinum as a pupil. Empedocles may have been a doctor too, but he was a great scientist, a great poet and a great fakir. We don't see that combination in such perfection today, but there are suggestions of it. He was par excellence the primitive medicine man and the modern scientist rolled up in one. In him the cave man greets us fraternally across the abyss of time. In the interest of his vanity or his safety, as Satyrus in a discussion of the ancient dialectics of the sophists intimates, he was master of the art of persuasion. In his time Empedocles had his fellow townsmen following him as though he were a god, as he said he was.

In the *Gorgias* (459 b.) the implication of the discussion at one time is that the physician ignorant in his art is frequently, by virtue of his art of persuasion, better able to influence the patient than the scientist. This is no secret, either ancient or modern, but it is interesting to see the thought of Socrates, that is without doubt here—of Plato, who well knew the Sicilian school of medicine, drifting back to Empedocles. The ethical aspect of this is further developed in the *Phaedrus* (261) where Gorgias, the Sicilian, is again to the fore in the mind of Plato and we are asked to believe that the more well versed one is with the varied aspects of the truth the better orator one may become. Under the scalpel of Socrates we see the doubting of this, doubt itself being an offspring of greater knowledge and a paralyzer of convincing oratory. The more eloquent rhetorician is he who knows just enough of his subject to believe implicitly in its dogmas.

In this connection we get here the mention of Hippocrates declaring that to understand man's body in a medical sense one must be acquainted with his soul. Which sentiment, while it occurs elsewhere in the Hippocratic Corpus, and which Galen ascribes to *The Nature of Man,* Littré thinks proves Hippocrates II was the author of *Ancient Medicine.* That may indeed be, but the more one reads Plato, the more one reads Hippocrates, the more one is convinced that much of the sententious wisdom which their books contain was current in the social body of Hellenic civilization of the time. We pick it out of Plato and Hippocrates when it falls in with the wisdom of our own time and because it is for the most part *their* books, only, survive. As a matter of fact such things are the wisdom of the ages. They are the A B C's of the wise man wherever and whenever he lives. Of course one talks best, orates most successfully about things in which one is most interested and the majority of intellectual men are interested only in things they partly comprehend. It is only the dullard loves to con over every hour a well known lesson. It is the social ass who is continually repeating it aloud. When Socrates and Hippocrates insist that the medical man must know other things than about man's body, if he expects to be a good physician, even they are but repeating the ordinary common sense of any civilized society. To use this as an argument that Plato was a plagiarist, in as much as Dupréel finds these sentiments in the *Dissoi Logoi,* which appears to have been notes taken by some student following Athenian lectures before or at the time of Plato's activity, is absurd. According to such a criterion Wells is the greatest of modern plagiarists.

Although in the *Nature of Man* and in *Ancient Medicine* there is no questioning the maxim that to speak properly of medicine we must know as much of the art as possible the author or, if there were two of them, the authors, insist that a knowledge of the bases of the other sciences lend persuasiveness to their discourse by exhibiting it. *The Airs Waters and Places* and *The Ancient Medicine,* in which this is so prominent a feature, are by far the most interesting books in the Hippocratic Corpus and, it happens, those which contain information still of good currency in the world of today. Now the teaching in the *Phaedrus* and in other books of Plato's, aside from the mocking irony of Socrates, is to the effect that to apply it specifically to our own interests, the knowledge of science outside of medicine must in the nature of things be more or less superficial. Yet the physician not only adds to his own storehouse of wisdom, but to the force of persuasion in his discourse. Pericles, Socrates insists, found it did when he spoke to the citizens of Athens on political subjects, resting on what he learned from Anaxagoras. The wonderful speech of Pericles, as given by Thycydides, implies this also. One may be sure Socrates laid open the subject so that one is reminded not alone that Pericles persuaded and ruled the Athenians, but for all that had not sufficient wisdom to bring up his sons properly. He makes us aware, too, of the pretence and ostentation that often goes with this sort of "persuasiveness." We still well know of such sons as those of Pericles. We still are well acquainted with the vanities of man. They are among the great human forces which move the universe.

Historical Note on Smallpox and Inoculation.—Dr. Charles Greene Cumston (*Annals of Medical History,* December, 1924) says that the practice of inoculation was introduced into America at Boston by Dr. Zabdiel Boylston in 1721 and later into Germany. Boyer's thesis upheld in 1717 at Montpellier is interesting because "it is the first French work in which reference to inoculation is made, and also because the thesis was published one year before Lady Montagu had her only son inoculated." No further attention was paid to inoculation in France until fourteen years later, when Marcot made a public address advocating it. But the first inoculation practised at Montpellier was performed by a physician at Nimes. The first inoculation was given on May 15, 1757, from a thread impregnated with virus which had been obtained from Geneva. Dr. Tronchin, who had inoculated the children of the Duke of Orleans that same year, was probably the donor of the virus. Dr. Cumston quotes from Gschwend of Switzerland to show that paralysis was often a sequel to smallpox in former days.

Contributors to the Science of Medicine

Thomas Linacre

Thomas Linacre was probably the greatest scholar who was also a doctor of medicine, not even excepting the great Sir Thomas Browne of immortal memory. It may be said of Dr. Linacre that in spite of the fact that he did much for medicine he was first of all a scholar, then a medicine man. Thomas Caius, also a physician and of immortal memory, did homage to Linacre in an epitaph on a stately monument surmounted by a phoenix in old St. Paul's, London.

It is now four hundred years since Linacre founded the Royal College of Physicians, London, and became its first president. Little is known of the early years of Linacre. Friend, in *A History of Physics,* Volume II, says that "Canterbury gave him his birth in 1460 and Oxford his education, he was chosen Fellow of All Souls." It must be understood that at the time Linacre went to Oxford that university was at a low ebb as far as learning was concerned. Wood describes the conditions as being in a very bad way and the Greek language being almost forgotten. It is the special glory of Linacre that he became the restorer of learning in England, that he revived the study of Greek and of the Greek medicine of Aristotle, Galen and Hippocrates. Linacre translated many of the works of Galen into English.

THOMAS LINACRE

When at Canterbury, he came under the care of William de Selling, a noted churchman of the time, who had already been in Italy, had studied Greek, and had brought back manuscripts to Canterbury. In 1488 Selling was sent by Henry VII on an embassy to the Pope and took Linacre to Italy with him and left him at Bologna which was then the seat of one of the celebrated universities of the world. He is next heard of at Florence at the court of Lorenzo de Medici named the Magnificent, where he associated with the master spirits of the age; indeed he may have sat at the same board with Michael Angelo. After staying in Florence for a year or longer he went on to Rome where he came under the influence of another great scholar, Hermolaus Barbarus. It was at about this time that he had access to the Greek manuscripts of Galen from which he made the translations published many years after. We next hear of Linacre at Venice, the friend and companion of the great scholar and printer Aldus. Linacre was one of the earliest of the English students to seek a medical education at Padua, then and for long after one of the most famous schools in Europe. On his way home from Padua he visited the renowned Nicolaus Leonicenus of Vicenza, one of the first and most distinguished of the medical humanists and author of the earliest treatise on syphilis then beginning to rage in Europe.

It is not accurately known how long Linacre stayed in Italy. When he returned to Oxford he resumed his teaching of Greek and probably practised medicine. Among those who studied Greek with him was Erasmus, who became his lifelong friend. Linacre, Grocyn and Latimer undertook the translation into Latin of the works of Aristotle, the father of physiology. In the meantime, Linacre's reputation as a scholar and also as a physician was increasing, but in or about the year 1500 his peaceful academic life was interrupted by a call to court to act as tutor to the son of the King, Prince Arthur. Soon after this he became the King's physician. At this period and for some years after there was a close relationship between the medical and clerical professions. It was no uncommon thing for a learned divine to practice physic and on the other hand a considerable number of distinguished physicians went into the church. Linacre joined the group and in 1509 and in succeeding years was given several valuable livings. From a statement made to his friend, the Archbishop of Canterbury, he seemed to have taken orders with a view to obtaining the necessary leisure for his literary work. He was still in practice, and with the organization of the Royal College of Physicians in London and his benefactions to the Universities of Oxford and Cambridge, his life was one of great activity. On October 20, 1524, he died from stone in the bladder.

As said before, Linacre was before all a scholar and played a great part in the revival of learning in England. But at the same time he has a very special claim on the medical profession as a medical humanist and as a leader of that band of fifteenth and sixteenth century scholars who sought to break the Arabian domination and to restore to medicine the teachings of Aristotle, Galen and Hippocrates. The revolt against the rule of Arabian medicine began and was fostered in the North Italian Universities. Not only were the works of Hippocrates

and Galen translated, edited, and published, but also those of Aristotle and Plato. The Greek ideals were brought back to medicine and observation and experiment were again made the chief aims of medical science.

As mentioned previously, Linacre translated and published many of Galen's works. In truth Linacre gained greater and more widespread fame as a grammarian than as a physician. His two works on grammar bore his name and fame into regions to which the name of the English physician had never penetrated. As Osler says in his fascinating sketch, Linacre may well be the old grammarian of the well known poem of Browning who doubtless got the idea from Erasmus. The following are two of the verses:

Back to the book then: deeper drooped his head;
Calculus racked him.
Leaden before, his eyes grew dross of lead;
Tussis attacked him.
"Now, master, take a little rest,—not he!"
Not a whit troubled,
Back to his studies fresher than at first,
Fierce as a dragon.
So with the throttling hands of Death at strife,
Ground he at grammar;
Still through the rattle, parts of speech were rife,
While he could stammer
He settled Hoti's business—let it be!
Properly based Oun
Gave us the doctrnie of the enclitic De,
Dead from the waist down.

Linacre was well acquainted with the North Italian Universities, the most flourishing of his day, Padua, from which he graduated, Bologna, Ferrard and Pavia. He knew their medical schools, some of them in towns smaller than Oxford and Cambridge, to which went students from all parts of Europe. At both Pavia and Padua in 1467 there were thirty-five well paid teachers in the medical faculties. Linacre endeavored to organize medical faculties at Oxford and Cambridge after the manner of the North Italian Universities and with this end in view made provision for two lectureships at Oxford and one at Cambridge.

However, Linacre's name is indissolubly associated with a more important foundation by far, the College of Physicians of London of which he was one of the founders and the first president in the year 1518. Somewhat curious to relate and a fitting commentary upon the conditions prevailing as regards medicine and surgery, the license to practice medicine was in the hands of the church. There were a few physicians who were often churchmen, a few surgeons, but the bulk of medical practice was done by barber surgeons and apothecaries. The original charter of the College of Physicians of London allowed it to regulate the practice of physic in London and for seven miles around. Four years later the privileges of the college were extended over the whole of England. Only graduates of Oxford and Cambridge were allowed to practice without a license and it was many years before the bishops gave up their rights. A remnant of this ecclesiastical privilege still persists. The Archbishop of Canterbury has the power to confer a doctorate of medicine, known as the Lambeth degree.

Among the Linacre lecturers at Cambridge sixteen have reached the distinction of the Dictionary of National Biography. Among these the most interesting names are William Heberden and Thomas Watson. Heberden, known as the English Celsus, was Linacre lecturer from 1734 to 1738 and his commentaries, although written in Latin, remain an English classic. Thomas Watson, the lecturer for 1822-26, was one of the cultured physicians of the nineteenth century, whose textbook, a model of literary style, still holds its own on account of its admirable clinical description of disease.

Thomas Linacre will live as a mighty Greek scholar and grammarian and as one who did most to restore the Greek spirit of medicine to the English medical profession.

The Ceraunia or Thunder Axe; Its Use in Folk Medicine.—Dr. M. A. van Andel, of Gorinchem, Netherlands, writes (*Annals of Medical History*, December, 1924) that not only in the countries of Europe, but also in many Asiatic countries, such as India, Burma, the East Indian Archipelago, China and Japan, and also in Africa and Brazil, do many of the present inhabitants believe the arrow heads, flint axes and mallets unearthed from prehistoric mounds or turned up by the plough to be "thunder axes" created by flashes of lightning penetrating the ground where the objects were found. Such a ceraunia or thunder axe, they believe, will rise to the surface in from seven days to seven months or seven years, and will protect any one who finds it from lightning, evil and disease, and give him the magical powers of being able to fertilize fruit trees, protect babies from witches, and promote a prompt delivery. To the Germans, these objects were the hammer of Thor. In Japan flint arrowheads were thought to have rained from Heaven, or been dropped by flying spirits. Pliny described them and their protective and curative uses, and ascribed their origin to a flash of lightning. Boetius is sceptical and inclined to think these objects might be stone tools very much like iron ones in use in his day, were it not for the fact that trustworthy witnesses have assured him that they found such stones in trees or houses recently struck by lightning. Therefore he deduces the hypothesis that such stones are formed by terrestrial exhalations which are condensed in the atmosphere and flung back to the earth when the cloud containing them bursts during a thunderstorm.

The Dutch naturalist, Ramphius, says the natives and Chinese dwellers of an island of the East Indian Archipelago think that these prehistoric remains are the teeth of a great bull who roars in the heavens and spits out his teeth which fall to the earth. Rumphius, however, does not admit this superstition, but concocts a theory somewhat like that of Boetius, explaining the peculiar shape by astral influence. The stones were used in the island as amulets to procure invulnerability, and to cure feverish diseases caused by a wetting from a thunderstorm. He tells us that in the Low Countries such stones are used as medicine. Herdsmen try to cure sick cattle by having them drink the water in which such a stone has been laid, and women with ulcerated breasts rub them with these stones to alleviate the inflammation.

In Saxony these relics were thought to protect their owners from nightmare.

MEDICAL PROGRESS IN 1924

A brief survey of the medical and scientific literature of the year 1924 will show the most significant and practical advance in medical science to be the greatly increased scope and content of public health work. New York, both city and state, has taken definite steps in this direction, the former in its intensive health demonstration in the Bellevue-Yorkville district; the latter, among other ways, in its inauguration of the demonstrations in Syracuse and Cattaraugus County. The United States Public Health Service has made a number of intensive studies and investigations, some of which are still in progress. The most notable of these are, perhaps, the survey of the health departments of one hundred cities of seventy thousand population and over; a study of common colds, especially in their relation to industry; and an investigation of conditions in industries presenting large occupational hazards. Allied to this last problem has been the awakening of interest in the prevention of carbon monoxide poisoning, especially as an industrial hazard, and also as related to the use of gas heaters in living quarters. Another important contribution to public health has been the surveys of the American Child Health Association in nearly one hundred cities of the United States. Accidents from automobiles have increased so greatly in number that a conference on motor vehicle traffic was held last spring in New Haven, the proceedings of which were published by the Yale University Press. The use of iodine as a preventive of goitre, a serious health problem in the Great Lakes region, has been studied and experimented with as a step toward establishing a definite program of treatment.

Probably the most important event in scientific medicine of 1924 was the isolation of the streptococcus as the definite causative agent of scarlet fever, the discovery that this organism produces a soluble toxin, that almost certain prevention is possible through the use of an antitoxin, and that immunity can be demonstrated by a cutaneous test. A large part of the above investigations were carried on by Dr. George F. and Dr. Gladys H. Dick, of the McCormick Institute for Infectious Diseases, Chicago. Other discoveries of the greatest significance but too well known to the medical profession to need more than the briefest mention are those of Dr. Moellgard of Copenhagen and Calmette of Paris in regard to tuberculosis, who are experimenting along lines of both prevention and cure. The theory of the cure and treatment of rickets by sunlight has received significant confirmation through a number of different studies and experiments carried on in various localities.

Other activities of perhaps secondary importance have been a survey made as follows: a study by the Department of Agriculture of the ripe olive problem as a menace to public health; the mosquito control work in the Canal Zone, which has resulted in rendering that region practically mosquito free; and successful activities toward the sanitation of bathing places and summer camps. Steps in public health education have been taken toward the prevention and care of the increasing number of cases of heart disease, cancer and diabetes. A number of the larger cities of the United States have launched projects along health lines, as for instance the child guidance clinics of Minneapolis, St. Louis, and Dallas. Boston opened on November 1st a new health unit, in the North End, and Columbia and Johns Hopkins Universities have both added to their facilities for teaching and research in psychiatry. Columbia University and the Presbyterian Hospital had made good by the end of the year in their campaign for funds for the new medical centre now in course of construction at Broadway and 168th Street, Manhattan.

It is both profitable and encouraging to review such steps as the above, and realize that the fact that they are taken means that the gap between the theory and practice of medicine is gradually closing, and that in the not far future doubtless much of the waste and duplicated effort in public health activities may be eliminated.

ENCEPHALITIS LETHARGICA

Sleeping sickness, socalled, an obvious misnomer as it is apt to be confused with the genuine sleeping sickness, is the most mysterious disease which has come into the limelight in recent years. Its origin is almost as obscure as when Economo and von Wiesner first called attention to the disease as an independent one, no longer ago than 1907. Since that time so much interest has been taken in the subject that its literature is now portentous in extent. Epidemics and sporadic cases of the malady are appearing continually in various parts of the world and naturally those engaged in medical research are agog to discover the cause. A short time ago the British Ministry of Health published a memorandum on encephalitis lethargica, in which the main and most salient facts relating to the disease are set down fully. It is pointed out that it was at first thought to be a form of botulism, and then as the cerebral form of

acute poliomyelitis, but detailed, clinical, epidemiological and pathological investigation has resulted not only in its identification with the clinical forms described previously in Vienna, but also in the elucidation of encephalitis lethargica as a distinct disease.

Of course, encephalitis lethargica has been put down as a form or type of influenza, and in spite of the weight of evidence which goes to show that it is an independent disease, there is yet much in favor of the former theory. Dr. Smith Ely Jelliffe, writing on the nervous syndromes of influenza in Crookshank's *Influenza* published in 1922, has a great deal to say concerning lethargic encephalitis. He points out that this type of disorder has been reported as occurring all over the world since the beginning of the 1915 epidemic of influenza. Whether, however, the influenza bacillus, if there is any one bacillus causing influenza, is able to cause a type of lethargic meningoencephalitis which Jelliffe describes, is still to be proved, as he himself admits. Moreover, he draws attention to the fact that the cases hitherto reported have all the features of an acute infectious disease, and he also draws attention to the fact that in the epidemic of 1889-91, such case reports began to appear in the literature. Henry Young called it grippe catalepsy, and Louguet, in 1892, referred to many of the cases as attributed at the time to influenza.

Strauss and his colleagues believe that they have isolated a specific filtrable virus; others have reported negative findings. Jelliffe thinks that it seems to be indicated that a definite polymorphism is present which points to the fact that there may be several agents, among which the influenza organisms are among the more prominent, capable of producing grave mesencephalitic lesions.

It is true that a virus has been obtained from the nervous tissue and nasopharyngeal mucosa of those suffering from the disease and a virus having similar properties has been obtained from the mouth of a healthy contact: these bear a close resemblance to the virus or herpes febrilis. But much further experimental work is needed ere any definite statement can be made.

It has been pointed out that minute bodies have been found in the tissues, the exact significance of which remains to be seen. It really seems from several aspects that it is almost as likely to be an outcome of influenza as an independent disease. But the cause or causes of influenza are not decided, seeing that the Pfeiffer bacillus has fallen into disrepute as the cause. The main features of encephalitis are that it attacks the central nervous system, producing lethargic, frequently almost cataleptic symptoms, that its mortality is high, that it journeys through the world in a slow march of epidemic character, leaving in the wake of its acute stages, serious, often disastrous aftereffects, and lastly, that no reliable therapeusis for the disease itself or for its sequelæ are known. Both from the bacteriological and clinical points of view the deadly disease of obscure origin and calamitous aftereffects require much further study and close investigation.

NEW LIGHT ON HUMAN DEVELOPMENT

A matter of two years or so ago, the scientific world was stirred by the announcement of the discovery of the Rhodesian skull, a relic of primitive man of the Neanderthal type which lived in Europe in Paleolithic times, maybe between thirty or forty thousand years ago. Recently, a discovery of a more sensational character has been made in South Africa. Professor Raymond Dart, of the Witwatersrand University, Johannesburg, states that he has discovered a fossil ape man, unlike any existing anthropoid, and more nearly resembling man, than the fossil remains of any ape yet discovered.

Professor Dart is now engaged in writing a monograph on the subject and pending the publication of this, final judgment must be reserved, but a sufficient account has been written by the discoverer in *Nature*, February 7, 1925, to justify the conclusion that the discovery will constitute one of the most important contributions to the solving of the problem of man's origin and evolution that up to the present time has been made. The skull was found in a limestone quarry eighty miles north of Kimberley on the eastern frontier of Bechuanaland. It may be recalled that the skull of the famous Rhodesian man was found deep in the bowels of a limestone hill. Australopithecus Africanus, the name given to Professor Dart's manlike ape, is said to approximate to man more closely in those important characters which are regarded by anthropologists as significant, than any fossil remains of a similar nature as yet found.

According to the description in *Nature* the cranium as a whole is distinctly humanoid in character. This is particularly apparent in the harmonious relation of the length of skull from front to back and the length of face, which in all apes are disproportionate to one another, and also in the slope of the forehead, which does not recede in the same degree as in the ape. The prominent eyebrow ridges with their lateral expansion, characteristic both of ape and the Neanderthal man, are entirely absent. The lower part of the face does not project nor does the chin recede as in the chimpanzee and gorilla, or even as much as in the Piltdown skull. The whole form of the jawbone is significant for,

while it is heavier than that of man, it is distinctly lighter than that of the anthropoids. The teeth are humanoid in character but immature as the specimen was young.

As Sir Arthur Keith has pointed out the size of the brain becomes the anatomist's criterion of humanity. The human brain varies in size; it may go up to 1,900 c.c., it may fall as low as 950 c.c. We do not expect beings who fall below the minimum of the scale to be capable of reasonable conduct. Among chimpanzees the brain varies in size from 320 c.c. to 490 c.c., among gorillas, from 370 c.c. to 620 c.c.

Thus between the highest anthropoid ape and the lowest living human being there is a wide gap. This gap is filled by the fossil man of Java, Pithecanthropus, in which the brain volume was 850 c.c. The Java man is a real missing link and in the sense perhaps Australopithecus is not a missing link, although the fact must be taken into consideration that the natural cast of the interior of the skull has suffered some damage and the individual had not attained maturity and it is believed that the brain of this specimen in the adult stage would exceed that of the gorilla. Probably, however, the size and marking of the brain cast fix the position of Australopithecus as a link in the evolutionary chain of anthropoid apes.

Two questions present themselves in relation to this discovery, that is to say to those who believe in the evolutionary origin of man, where does this being stand in the line of human development and, secondly, how far does this discovery throw any light upon the place of origin of the human race. It would be premature to pass an opinion on either of these points, which will no doubt be dealt with in the monograph by Professor Dart, which will be published shortly. However, with regard to man's place of origin this may be said.

The discovery of Pithecanthropus erectus in Java in 1891 and of fossil apes bearing some resemblance to man in the Himalayas have directed attention to the plateau of Central Asia as a likely locality. As a matter of fact, it is hoped that this is a question which the great American paleontological expedition now working in Asia may help to elucidate. But these recent discoveries in South Africa as well as that in Egypt of a fossil ape thought to be ancestral to both the simian genus and man, may require a modification and perhaps a total revision of existing views.

It may be added that Dart is the young professor of anatomy in the medical school at Johannesburg and was trained in London under one of the greatest anatomists of the world, Professor J. I. Wilson.

THE LEAGUE OF NATIONS AND MALARIA

In Eastern and Southeastern Europe, in many parts of which malaria is endemic, the disease extended its area and prevalence during the war and has continued to extend since the conclusion of the war. In districts of European Russia malaria is present during the winter and rife in the summer. In Macedonia, it is extremely prevalent, and the same may be said of Albania. It is therefore encouraging to learn that definite steps for dealing with malaria in Europe have been adopted by the League of Nations Health Committee, the second session of which has recently concluded in Paris. A subcommittee for several months has been dealing with the malaria problem. This subcommittee is shortly to visit Jugoslavia, Rumania, Russia, Ukraine, and Italy in order to gain full and reliable knowledge of the actual situation in the countries visited. At the request of the Albanian Government Dr. Haigh, a former member of the League Epidemic Commission, has been commissioned to complete a survey he has already begun of malaria in Albania, and to present a report on the basis of which the malaria subcommittee will prepare a technical plan for the use of the Albanian Government. The subcommittee is also receiving reports from Great Britain, Denmark, and Holland, where malaria has been stamped out or almost stamped out within recent times, as well as from those countries in Southeastern Europe where malaria has spread greatly since the war. With the preliminary knowledge gained from these investigations, it is hoped that an effective international campaign can be carried out. The question of the supply of quinine—it really is not so much the limited supply but the great cost—as well as the efficacy of quinine and other cinchona alkaloids, will also be studied. It was decided recently that an Epidemiological Intelligence Bureau should be set up in the Far East by the League of Nations. The Health Committee has recommended to the League Council that this Bureau should be established in Singapore.

Malaria is easily the most destructive disease to life and health known. There are other diseases, as plague, for instance, which are more fatal, but there is no disease which at the same time is so harmful to health and so widespread as malaria. Treatment is more or less futile so far as the abolition of the disease is concerned. There is no malady to which the old maxim—prevention is better than cure—applies so aptly as to malaria.

Ross, when he discovered the mode by which malaria was transmitted, showed himself to be perhaps the greatest benefactor of his age, as he pointed out also the way for its extirpation. He has constantly

preached that if the breeding places of the mosquitoes are destroyed, malaria will disappear. This is selfevident and has been proved times without number, but has rarely been carried out on large scale, the excuse being the vast cost of such undertakings. Of course draining marshes and swamps would be an immense expense, but if the outcome be regarded the question of expense fades into insignificance. Not only would the most debilitating disease of the world be abolished, but large tracts of land would be rendered fit for cultivation and in the long run the cost would be returned over and over again in health and prosperity. The malaria problem, as Ross himself has constantly pointed out, has never been grappled with in the only way which is certain to bring results and which would remove from the tropics one of the greatest drawbacks to lands of the Torrid Zone as places of residence for white men. Many of the worst diseases of the tropics are carried by insects and the prevention of such diseases can only be attained by getting rid of the hosts.

INFLUENZA

It is some years now since a pandemic or even a large epidemic of influenza struck terror into the inhabitants of the entire world, and it is curious to note how soon human beings forget the ills that have beset them, however grievous they may have been. In the instance of influenza it is unwise to let pass from the memory a disease of so far flung and protean manifestations, because it seems certain that another pandemic will occur, perhaps sooner than expected. The views as regards influenza are diverse, both as to cause and treatment. According to Crookshank in a work on influenza consisting of essays by several authors, which he edited and which was published in 1922, to ask what is influenza? and what is the cause of influenza? is unscientific regarded from certain viewpoints. He points out that when we speak of ascertaining the nature of influenza, and of discovering its cause, what we are really implying is the need for testing, in agreement with the method of science, the accord of our available experiences with the empirical generalization which is loosely expressed when we say there is a disease which we call influenza, and there is a need for further shaping and defining this empirical generalization in memory with our experiences.

However, perhaps the most moot point with respect to influenza is as to whether the socalled influenza bacillus, Pfeiffer's bacillus, is the cause of the disease, or what is the relation it really bears to the infection. Up to the time of the latest pandemic, Pfeiffer's bacillus was regarded generally as the cause, but the investigations taken in 1918 threw doubt upon this and the question now is thoroughly confused. In Crookshank's *Influenza* the matter of the bacteriology of influenza, with special reference to Pfeiffer's bacillus, is closely considered by Dr. Robert Donaldson, pathologist to St. George's Hospital. In fact, no such acute analysis of the problem has, perhaps, been done before or since. It may be mentioned that when Pfeiffer published his preliminary paper in 1892, some bacteriologists working along the lines he laid down were able to corroborate his findings. Others, notably in France, frankly refused to acknowledge that the bacillus was in any way chronologically related to the disease. Donaldson points out that all that Pfeiffer was entitled to infer from the facts stated in his papers is this, that in all the cases examined by him in November and December, 1891, amounting in number to thirty-one, the small gram negative bacillus isolated therefrom stood apparently in some etiological relationship, though whether as a primary or secondary agent it was not possible to say. Pfeiffer utterly failed to communicate the disease to animals, and lastly, the bacillus is not the only one of its kind, and the term Pfeiffer's bacillus may really connote, not one particular kind of bacillus, but a group of more or less closely related bacilli. Donaldson then proceeds to review in detail, in the light of research carried out during the pandemic of 1918, the reasons for or against the acceptance of Pfeiffer's bacillus as the cause of influenza. The review is done most thoroughly but owing to lack of space only a few points can be referred to.

MacCallum visited three different places in America in 1918, and made cultures from the lungs of persons who had died from influenza. He used the same technic and the same media throughout. At Camp Dix he isolated Pfeiffer's bacillus in one hundred per cent. of the twelve cases examined. At Camp Lee he recovered the bacillus in only thirty per cent. of the cases and two of the six positive were doubtful. Finally, at the Johns Hopkins Hospital he examined sixteen cases and failed to find Pfeiffer's bacillus in one. The inference to be drawn from a consideration of these various results obtained seems fairly obvious. Others engaged in investigating material derived from widely different sources simultaneously have had similar experiences. The failure can have only one meaning, that Pfeiffer's bacillus was not actually present in the majority of the cases of influenza examined.

Donaldson remarks that its absence in even a much smaller percentage would still invalidate the claim of the organism to be regarded as definitely causal for influenza. In short, Donaldson argues that whatever be the cause of pandemic influenza, all the observed facts go to prove almost conclusively that

it is not Pfeiffer's bacillus as classically described. He also thinks that there is not the slightest shred of evidence that the disease is due to a socalled filter passing virus, and he criticizes adversely other suggested causes. He draws attention to the fact that there is a very strong possibility that the assumption of a single specific and unvarying virus common to all cases of pandemic influenza is entirely erroneous. Morbid lesions in general are results of invasion of organs by living cells, whether of extracorporeal origin, bacteria and protozoa, or of corporeal derivation, the various tissue cells. So long as the first named remain on the outside of the body and the second observe their proper frontiers, the body is in a condition of health.

Much is known about the types of invading about the extraordinary diverse types of invading cells, the results of their activity after entry into the body, and the reactions induced thereby, but relatively little is known concerning the why of their invasion. Increased virulence is but a partial answer Donaldson suggests—is not the true solution to be found in an exact understanding of the mechanism of the first line of defence, and of how that mechanism may be altered by physical causes operating from without, and biophysical causes acting from within? Influenza provides a fruitful field for investigation and to a greater or less extent it is almost always with us, although apparently the type of the disease changes as the epidemic develops. How does the disease spread and are the popular views held by epidemiologists as to the manner of its spread correct? It is possible that the disease is not always spread by contagion. On the whole, influenza is the most mysterious disease known, the secret of which is still far from discovery.

CARBON MONOXIDE POISONING

An editorial in a recent issue of *The American Journal of Public Health* summarizes the dangers arising from the use of gas as fuel, and gives some statistics of deaths and asphyxiation from carbon monoxide gas from domestic heating appliances. The flueless gas heating stove is responsible for most of the poisoning in this country, and of these the so-called radiant heater has been found to be the most dangerous. Gas water heaters have also caused some deaths and asphyxiations.

During the winter of 1922-23 in Ohio there were sixty-four deaths and one hundred and thirteen cases of partial asphyxiation. Of these forty-one deaths and forty-six asphyxiations were due to heaters, generally of the radiant type. In the winter of 1923-24 there were in Ohio sixty-one deaths, forty-two of which were due to gas heaters. These statistics were compiled by the State Board of Health, and not taken from newspaper reports.

The best way to prevent asphyxiation by gas heaters is to have an abundant supply of flues to carry off the waste products. The heaters should be se back in the fireplace so that the flue in the chimne can carry off the fumes. Special care should b taken that the flue is kept open and unobstructed Water heaters in bathrooms are particularly danger ous on account of the small size of the rooms, and th fact that they are kept closed while in use. Instan taneous heaters are especially prone to generate car bon monoxide very fast. In a bathroom of ordinary size, enough gas can collect in fifteen minutes t asphyxiate a bather.

The automobile is another source of dangerous gas hence all garages should be well ventilated and hav doors opening outward. The engine should never b allowed to run in a closed garage, and it is espe cially dangerous to get under a car when the engin is running.

Since carbon monoxide gas has no odor, taste color, nor irritant action, it can be present in larg quantities without being perceived by the senses One tenth of one per cent. in the air will cause fata results in a few hours. "It has three hundred time the affinity for the blood that oxygen has, and form a stable compound with hemoglobin in the red bloo cells which is not easily broken up. In addition t the acute, there are many cases of more or les chronic poisoning, in which the symptoms may var from slight discomfort to extreme ill health. A wor to the wise is sufficient."

Obituary.

SIR EDWARD THORPE, C.B., D.Sc., F.R.S

London

Death has been busy of late among the scientific men of Great Britain. In succession to Sir James Mackenzie and Sir Clifford Allbutt, Sir Edward Thorpe, one of the best known chemists of his generation, died on February 23d. Like Sir Clifford Allbutt, he had reached a green old age as he was in his eightieth year. He was born near Manchester and after attending Owens College, studied at Heidelberg under Bunsen, and at Bonn. In recent years he will perhaps be remembered chiefly for his presidential address to the British Association in 1921 on the mechanism of the atom. Thorpe also did remarkable work in magnetic surveys and took part in four solar eclipse expeditions. He had held many offices in the learned societies of this country, and was a member of kindred bodies in America and Europe.

He had been president of the Chemical Section of the British Association of the Chemical Society and of the Society of Chemical Industry, Fellow, Foreign Secretary, and Vice-President of the Royal Society, and President of the British Association. Some of his works, such as *Chemical Problems, Inorganic Chemistry, Quantitative Analysis, Qualitative Analysis,* and *Dictionary of Applied Chemistry,* were generally regarded as authorities. An attractive and vivacious lecturer, Thorpe delighted in the study of the history of his science, and he published monographs on Dr. Priestley and Sir Humphrey Davy, *Essays on Historical Chemistry,* and a life of Sir Henry Roscoe, and a *History of Chemistry.*

News Items.

Red Cross Membership.—The American Red Cross announces a membership for 1925 of 3,360,000, a gain of about 237,000. With the exception of New England, the gain was general over the United States.

Typhoid Carriers.—A bill has been introduced into the Minnesota senate, providing that typhoid carriers who are prevented from earning a living, by health regulations, shall be eligible for compensation by the state. The industrial commission shall determine the compensation due in each case.

Crile Research Fellowships.—Two fulltime fellowships for the academic year 1925-26 are available for research at the medical school of Western Reserve University, Cleveland. Details may be obtained from the Committee on Medical Fellowships, Western Reserve University, 2109 Adelbert Road, Cleveland, Ohio.

Biggs Memorial Lectures.—As a memorial to the late Dr. Hermann M. Biggs, Mrs. Biggs has donated to the New York Tuberculosis Association an annual lecture on tuberculosis, to be given in New York by some prominent physician. The execution of the project has been transferred to the Medical Society of the County of New York.

Exhibition at Grolier Club.—An exhibition of early anatomical works was opened at the Grolier Club, 47 East Sixtieth Street, New York, on March 19th. The guest of the evening was Lt. Col. Fielding H. Garrison, of the U. S. Army Medical Corps, who said the collection of pre-Vesalian and Vesalian items surpassed anything of the kind he had yet seen.

Samuel D. Gross Prize.—The Philadelphia Academy of Surgery announces the award of the Samuel D. Gross Prize for 1925, amounting to fifteen hundred dollars, to Dr. John Alexander, Department of Surgery, University of Michigan Medical School, for his essay on "History, Present Practice, and Proposed Reform of the Surgical Management of Pulmonary Tuberculosis."

Neurological Institute Joins Health Centre.—The Neurological Institute has made plans for a new building near the Presbyterian Hospital and Columbia University medical centre, receiving land close to the proposed New York State Psychiatric Institute. The Neurological Institute, however, will not receive any of the money being collected for the centre, but will have to provide the money for its buildings. The present quarters on East Sixty-seventh street will be retained for diagnosis and observation. The president of the Institute, Robert Thorne, has become a member of the Joint Administrative Board.

Personal.—Dr. Joseph S. Halstead, of Breckenridge, Missouri, recently celebrated his one hundred and seventh birthday.

Dr. M. Joseph Mandelbaum has been appointed attending otolaryngologist to the Hospital for Joint Diseases, New York.

Dr. Frank G. Boudreau, chief of the division of communicable diseases of the Ohio Department of Health, has accepted the position of statistician-epidemiologist with the League of Nations.

Dr. George K. Pratt has become assistant medical director of the National Committee for Mental Hygiene, located in New York; he was formerly medical director of the Massachusetts Society for Mental Hygiene.

Dr. William W. Keen, of Philadelphia, celebrated his eighty-eighth birthday on January 19th. Doctor Keen is emeritus professor of principles of surgery and of clinical surgery at Jefferson Medical College, and has been in practice sixty-five years.

Dr. A. Strachstein has been appointed attending urologist to the Jewish Maternity Hospital.

Dr. Louis I. Harris, director of the bureau of preventable diseases of the New York department of health, has been elected president of the Association of Tuberculosis Clinics of New York.

Dr. Maximin de M. Touart has been appointed medical director of the Reconstruction Hospital, New York, and Dr. Seth M. Milliken, surgical director.

Dr. Virgil P. Gibney has been appointed surgeon in chief emeritus of the Hospital for the Ruptured and Crippled, New York, retiring from active duty after fifty-four years' service. Dr. William B. Coley has been appointed surgeon in chief to succeed him.

Medical Council for Visiting Nurses.—Dr. William Darrach, dean of the College of Physicians and Surgeons, is chairman of a committee of medical men to act as council for the Visiting Nurse Service of the Henry Street Settlement.

Rockefeller Foundation Gifts.—The Rockefeller Foundation has given 10,000,000 dinars (about $200,000) to Jugoslavia for the construction of a school of hygiene at Zagreb, the administrative capital of Croatia; $40,000 for the improvement of sanitary institutions in Belgrade, and $15,000 for the aid of needy students abroad who pledge their services after graduation to the public health service in Jugoslavia.

The American Board of Otolaryngology.—This board will hold its first examination during the meeting of the American Medical Association in Atlantic City, May 25th to 28th. According to its rules, applicants are divided into three classes: 1, those who have practised otolaryngology ten years or more; 2, those who have practised otolaryngology five years and less than ten years; 3, those who have practised otolaryngology less than five years. The examination is different for each class. The secretary is Dr. H. W. Loeb, of St. Louis, Mo.

American Psychopathological Association.—The fifteenth annual meeting of this association will be held in Washington, D. C., May 7th, at the New Willard Hotel. According to present plans the scientific program will be presented on the afternoon and evening, a subscription dinner to follow the afternoon program. A preliminary list of contributors to the program include Dr. Alfred M. Barrett, Dr. J. Ramsey Hunt, Dr. L. Pierce Clark, Dr. L. E. Emerson, Dr. Harry S. Sullivan, and Dr. Trigant Burrow. Dr. Sanger Brown, 2nd, is secretary of the association.

Approval of Pathological Laboratories.—To discourage commercial or unethical clinical and pathological laboratories, the Medical Society of the County of New York has made arrangements for granting certificates of approval when so warranted. The requirements are that the director of the laboratory shall be a licensed physician, and shall present an application blank from the Society, a license from the New York City Department of Health, and approval from the New York State Department of Health. Any form of division of fees or contract form of practice are prohibited, and display advertising is to be discouraged. Every facility to secure approval by the Society will be rendered on written communication to the Committee on Clinical and Pathological Laboratories, Medical Society of the County of New York, 17 West Forty-third Street, New York.

Society News.—The American Society for the Control of Cancer has elected the following officers: Dr. Howard Canning Taylor, president; Dr. Francis Carter Wood, vice-president; Thomas M. deBevoise, secretary, and Calvert Brewer, treasurer.

The Medical Women's National Association will hold its annual meeting May 25th and 26th at the Marlborough-Blenheim, Atlantic City. Women physicians attending the American Medical Association meeting will have their headquarters at the Marlborough-Blenheim; and will hold a banquet at the Ambassador, May 27th. Information may be received from Dr. Clara K. Bartlett, 4301 Atlantic Avenue, Atlantic City.

The Western Physiotherapy Association will hold its seventh annual meeting in Kansas City, Missouri, April 16th and 17th, under the presidency of Dr. L. A. Marty, of Kansas City. The Western School of Physiotherapy will hold its seventh annual session in Kansas City the preceding week.

At the annual meeting of the New York Electrotherapeutic Society, the following officers were elected: president, Dr. Norman E. Titus; vice-president, Dr. Harry E. Stewart; treasurer, Dr. J. Willard Travell; secretary, Dr. Richard Kovacs.

The American Association of Obstetricians, Gynecologists, and Abdominal Surgeons has elected the following officers: Dr. Asa B. Davis, New York, president; Dr. William E. Darnall, Atlantic City, and Dr. Henry Schmitz, Chicago, vice-presidents; Dr. James E. Davis and Dr. George V. Brown, both of Detroit, secretary and assistant secretary; Dr. William G. Dice, Toledo, treasurer; and Dr. James F. Baldwin, Columbus, Ohio and Dr. Edward A. Weiss, Pittsburgh, members of the executive council.

Foreign Correspondence.

LONDON LETTER

(*From our own correspondent*)

London, *February 20, 1925.*

THE APPROVED SOCIETIES AND HEALTH

The twelfth annual meeting of the English National Conference of Industrial Assurance Approved Societies, which have a membership of six million, was held on February 16th in London, with Mr. A. C. Thompson in the chair. In acknowledging the election Sir Amos Kirk, the president, said that national health insurance seemed destined to be the forerunner of other forms of national insurance, and probably the parent of that larger conception popularly known as "all-in insurance."

The provision of dental treatment as an additional benefit had proved an experiment of great value and would, he felt sure, be continued and extended. If, on financial grounds, dental treatment as a statutory benefit was found impracticable, he urged that the necessary sacrifice be made to provide dental treatment for all insured persons. While medical benefits might be extended to dependents of insured persons they must first see that they had provided their insured members with all the available aids for the prevention and cure of sickness before they attempted to extend the benefits. Sir Thomas Neill said that there were now thousands of insured persons suffering from tuberculosis, and he thought the societies should take up the work of obtaining better houses. One society alone had five thousand members suffering from tuberculosis, of whom one thousand were getting no treatment at all.

Mr. Neville Chamberlain, the Minister of Health, said that he had been making inquiries as to the scope of the societies' operations, and the results he thought would be somewhat of a surprise to the public, as they had been to him. He found that during the past year no less a sum than £14,000,000 had been paid in cash benefits and £10,000,000 in medical benefits. There were two other directions in which the assistance of the societies would be warmly welcomed. First of all, there was the position of the unemployed, and then there was the question of voluntary hospitals.

It was gratifying to find that the great efforts in the past had resulted in a considerable abatement of tuberculosis. They might fairly say it was on the decline today, and he hoped that it would be possible before he gave up the office to meet the difficulties of the problem. The conditions of housing had become absolutely intolerable, and they were doing all they could at the Ministry to develop the building of new houses on new methods. They believed that the question could no longer be dealt with by old methods, and it was their desire to see if they could find out in order that they might hasten the time when people would be able to live once more under favorable conditions of health.

NATIONAL DECAY AND REGENERATION

Dean Inge, who is known as the gloomy Dean because he does not gloss over the defects of civilization and of the people of Great Britain but who is really one of the clearest thinkers and most able speakers and writers of the country, spoke at Horsham, Sussex, on February 15th, on National Decay and Regeneration. He said he saw no reason whatever why a nation should grow old. If it perished it perished either from disease or violence. He said the history of the Roman Empire could be understood only if we realized that throughout antiquity civilization was in a state of siege. One assailant was malaria and another undoubtedly the internal disruption of the body politic.

The modern man might be a poor creature physically, but he had developed quite a new power of resisting microbes, and had become magnificently resistant to alcoholism.

As for the birth rate which was highest among the feebleminded, the Dean said the State did all in its power to increase the evil by throwing on the industrious the whole burden of maintaining in constantly increasing numbers the waste products of the social machine. We were breeding from the bottom and dying off at the top. If it were skilled workmen who were filling the cradles, there would be much less ground for alarm. It was the slum dweller, the untaxed dole receiver who was the father of the next generation.

There was no reason at all why a nation should not go on renewing its youth. That was not to say that we should always hold our present position as a great power. The area of our country was far too small. The future belonged to the large countries, especially to the United States, but the British Empire was a large country, and, taken together, ought to rank as one of the chief countries of the world. The race was far more important than the nation.

PRESERVATIVES IN FOOD

A somewhat stringent set of regulations with regard to preservatives in food has been incorporated into the new bill in this connection which is now coming before Parliament. These regulations have given rise to a considerable amount of discussion and many of those who deal in articles of food which contain preservatives are up in arms. Even some of the scientific authorities take the stand that so little is known concerning the deleterious effects of some of these preservatives and coloring matters, that it is unfair to prohibit their use. Boric acid is perhaps the preservative around which most of the controversy rages. However, it is undeniable that it is not fitting to add to articles of food any material not of the nature, substance and quality of food, which is the main contention of a Departmental Committee which has reported recently on the subject.

As Professor Henry G. Armstrong said the other day in an article published in the *Daily Telegraph*, the problem at the moment is how best to effect an economic compromise, so long as it be impolitic, if not impossible entirely to stay the use of preservatives. We know remarkably little of the action of preservatives, of the manner in which they serve to prevent objectionable changes. We are only clear that they hinder, if they do not suppress entirely, fermentative and putrefactive change.

Professor Armstrong enters into a discussion on the action of various preservatives commonly used, that is as far as is known, and points out that the fac-

tors at work in life are so numerous, it is so difficult to trace effects to their causes, that valid proof of injury will not easily be found. What we are learning is that the healthy body is built up during earliest childhood and that lost opportunities can never be regained. So that we should take every precaution not only to provide all that is necessary, but to avoid all possible sources of interference. In the case of marasmic children, the slightest interference may be fatal. He concludes that little as we know, vague as is our knowledge, all tends to show that we shall be wisehearted to avoid the use of preservatives as far as is possible. Attention may be directed to the fact that on the whole the laws as regards the employment of preservatives in food are more lax in this country than in America.

THE CAUSE OF TETANY

At a meeting of the Glasgow Royal Medico-Chirurgical Society held on January 26th, last, a discussion on tetany took place. Professor Leonard Findlay, after tracing the history of the disease, referred to the various hypotheses as to its pathogenesis and to the relationship of idiopathic tetany to tetania parathyreopriva and concluded by describing the investigations of Professor Noël Paton and himself, which have led them to the adoption of the guanidine intoxication hypothesis. Dr. Stanley Graham pointed out that the four main hypotheses held at present were: 1. Guanidine intoxication; 2. A disturbance of the ratio of sodium and potassium to calcium and magnesium; 3. Calcium deficiency; and 4. Alkalosis.

With regard to the guanidine intoxication hypothesis he was of the opinion that until more accurate methods for the estimation of guanidine were devised little further confirmation could be obtained. As for calcium deficiency, the association of a diminished calcium content in the serum with certain forms of tetany he had found to be by no means constant, and in two recent cases of active tetany the calcium content had been normal. Also in other forms of tetany, gastric and hypernoeic, the calcium content might be normal. In uremia with a low calcium content no instance of tetany had been recorded.

The disappearance of the signs of tetany on the administration of calcium chloride supposed to be due to the supply of calcium ions was now considered to be due to the acidosis produced. Ammonium chloride had been found to be as effective as the calcium salt, while calcium lactate failed to relieve the tetany. The acidosis of a gastroenteritis had been found to cause the signs of tetany to disappear. Dr. G. H. Clark believed the cause to be gastro-intestinal.

REVERSION OF £160,000 FOR MEDICAL RESEARCH

Mr. James Maxwell Grant Prophet, director of the Chartered Bank of India, who died in Calcutta on December 14th, last, left estate of the gross value of £219,793, the death duties bringing that amount down to about £160,000. He bequeathed £500 to the Staff Provident Fund of the Oriental Club and subject to a life interest his residuary estate for a trust fund of which one half is to be applied for inquiry into the nature, cause, prevention and treatment and cure of tuberculosis, and half for similar inquiry regarding cancer, as a board of special trustees shall decide.

LATIN AMERICA LETTER

(From our own correspondent)

BALBOA HEIGHTS, C. Z., *February 10, 1925.*

GUATEMALA REORGANIZES ITS HEALTH SERVICE

On the reorganization of the National Health Service of Guatemala, Dr. José Azurdia has been appointed president of the reorganized service and Dr. M. Muniz secretary. Following the example of other Central American countries, the Government of Guatemala is requesting funds from the Rockefeller Foundation for a cooperative campaign against hookworm and including other sanitary work. It is planned to run the campaign for at least five years.

The Rockefeller Foundation representatives are now doing some form of health work in practically all the countries of Central America. During the past year they have done exceptionally merited work against yellow fever in Salvador where an epidemic occurred the latter part of June, 1924. Had this epidemic gained headway, all the ports in Central America and the Canal Zone would have been menaced. Dr. Louis Schapiro, chief of the Hookworm Commission of the Republic of Panama and also a Rockefeller Foundation representative, is now on an extended tour of Central America studying the sanitary conditions in those countries.

VITAL STATISTICS OF THE CANAL ZONE

A total of 192 deaths occurred during the month of December, 1924, among the population of the Canal Zone and the cities of Panama and Colon, which is equivalent to an annual death rate of 18.42 per thousand. The leading causes of death were: pneumonia, thirty-three; tuberculosis, twenty-eight; nephritis, sixteen; organic diseases of the heart, sixteen; cancer, eleven. There were eight deaths from diarrhea and enteritis, five from bronchitis, and three from apoplexy. Of the total deaths, sixty-three, or thirty-three per cent. occurred among children under five years of age. There were twenty deaths among nonresidents of the Isthmus; these are not included in the above statistics.

There were 307 live births reported during the month, and thirteen stillbirths. Including stillbirths, this is equivalent to an annual birth rate of 30.71 in a thousand of population. Deaths among children under one year of age numbered forty-seven, giving an infant mortality rate of 153.09 in a thousand live births.

The total number of malaria cases reported during the month was ninety-nine. Of these, three were reported from Panama City, four from Colon, forty from the Canal Zone sanitated areas, and fifty-two originated outside of our unsanitated areas. Of the total, fourteen were employees, forty-seven were nonemployees, and thirty-eight were Army and Navy personnel. There were two deaths from malaria.

STRINGENT REGULATION ON ACCOUNT OF PLAGUE

Owing to the renewed presence of plague on the west coast of the United States and also on account of its ever prevalence in South America, the Chief Health Officer upon recommendation of the Chief Quarantine Officer has just issued the following instruction to shipping interests. The text of the instructions follows:

Instructions to owners, masters, and agents of vessels arriving at Canal Zone ports, and to all others concerned:

1. Attention is invited to the fact that bubonic plague is prevalent in many parts of the world and has recently occurred in certain important seaports of the United States. It is of the utmost importance to shipping interests that all practicable measures be taken for preventing the spread of this disease to noninfected territory, and it is imperative that the Panama Canal continue free from plague. Plague is primarily a disease of rats and from infected rats it is usually transmitted to man through the agency of the rat flea.

2. Inspections by the Quarantine Division reveal the fact that officers on many ships docking at Canal ports appear to be unacquainted with the details of the quarantine regulations relative to preventing the introduction of rats into the Canal Zone. This statement applies particularly to the placement of rat guards and the fending off of ships.

3. Metal rat guards of standard type, not less than three feet in diameter, must be applied to all mooring lines, must be in good repair, must fit the lines accurately, and must be approximated at all points. They must not overhang the dock and must not be nearer to it than six feet. Preferably they should be placed on the line about three feet from the ship. Where spring lines emerge from hawse holes and can not be protected with rat guards, then the hawse holes must be tightly covered with canvas or plugged with suitable material. Ships must be breasted off from the pier at least four feet unless other provisions are made by the Chief Quarantine Officer. Savealls, catchalls, cargo chutes, hose, and all other communications with the shore except gangways and properly rat guarded lines, must be disconnected from the dock when the ship is not working; gangways must be either raised at night or well lighted and guarded by a watchman.

4. The most common faults in the placement of rat guards on ships in the Canal Zone are:

a. Use, on double lines, of rat guards which were constructed to fit one line. b. Application of rat guards made for large hempen cables on small wire cables without first wrapping cable with burlap or other suitable material. c. Use of bent or broken guards which do not permit all openings in the disc to be closed. d. Placing rat guards too near the dock (less than six feet), thereby giving opportunity for rats to jump from cable to dock. e. Placing rat guards on crossed lines, or on lines close together, in such a way that rats may pass from one line to another, thereby allowing migration from one ship to the next, or from one ship to the dock by way of another ship's cable. f. Use of nonstandard rat guards, such as those with a diameter less than three feet or of conical shape. The conical guards soon fall out of position, enabling rats to walk over the edge and so get upon the docks.

5. Attention is invited to the fact that there are heavy penalties for nonobservance of quarantine regulations. While the Canal officials wish to facilitate shipping in every possible manner, they can not countenance nonobservance of regulations, thereby endangering the public health in the Canal Zone and on passing ships.

NEW LEGISLATION IN PANAMA

The National Assembly of the Republic of Panama has recently passed an organic law creating a National Health Department. This law has been signed by the President and immediately becomes active. A far reaching plan for the organization of this department has been drafted and presented to the President and his cabinet for study.

Dr. Luis Shapiro of the International Health Board has lent great aid in the drafting of the plan for the proposed Health Department and its far reaching activities.

Dr. R. M. Taylor of the International Health Board, who recently passed through Panama has gone to Costa Rica to take charge of the National Public Health Laboratory which was recently established in cooperation with the Rockefeller Foundation. This laboratory has been functioning for the past four months, and Dr. Taylor's directorship of the laboratory will be a large asset to the government of Costa Rica.

MALARIA IN THE ISTHMUS

On account of the recent development of a number of cases of malaria among the employees of the Canal Zone and the sudden death from this disease of the wife of an employee, the Health Department has issued a warning to all residents of the Canal Zone in reference to riding out into the unsanitated areas after night fall. The Health Department has frequently pointed out the danger of visiting the unsanitated areas of the Canal, yet it seems that the warning has been in various cases unheeded. It has been therefore considered necessary to repeat it. As compared with the early years of construction the Canal Zone has had few fatal cases from malaria, there are sufficient numbers to remind us that the Canal is not and probably never will be free from malaria bearing mosquitoes.

Owing to the curtailment of appropriations it is impossible for the Health Department to sanitate a very large area of the Isthmus but it does sanitate around the settlements for a distance of approximately one mile from the built up sections, this distance being considered sufficient to prevent the influx of the dangerous anopholes into town sites. The outer limits of the Zone are adjacent to the unsanitated areas so that a person just within the area of the unsanitated border is relatively less protected than those near the centre of habitation. It is considered extremely dangerous to leave the sanitated Zone, especially during the wet season and is not altogether safe at any time of the year.

HEALTH CENTRE ACTIVITIES RESUME

With the beginning of the new year increased activities in child welfare have occurred throughout the Isthmus of Panama. The examination of all school children has been completed and correction of the defects are now being conducted at the two main hospitals of the Canal. Parents are responding to the notices sent them relative to such corrections and scarcely a day passes that there are not less than five children undergoing operations for the different defects.

The centres for infants and preschool children have again opened up on both sides of the Isthmus and a new one has been formed at Pedro Miguel,

an important settlement. The mother's clubs are vitally interested in these centres and attend in large numbers.

A physician and nurse are on duty two afternoons a week for consultation. One of the large problems among the children of the Isthmus is the question of nutrition. The milk supply is relatively limited and only infants under two years of age or sick children can obtain the best supply of milk. A crusade has been on for some time to encourage parents to use milk powder supplemented with fruit juices.

Letters to the Editor.

SPLINT TREATMENT OF FRACTURES

NEW YORK, *March 11, 1925.*

To the Editor:

My attention has been called to a paper in the last issue of the MEDICAL JOURNAL AND RECORD by Dr. E. H. Bradford entitled "Splint Treatment of Fracture of the Neck of the Femur and Hip Disease." From this I quote as follows:

"It may be believed that freedom from plaster of Paris fixation aids in bone union. Before the introduction of plaster of Paris fixation, nonunion was little feared and bony union was to be expected, with joint stiffness, some shortening, and permanent disability. Since the introduction of plaster of Paris, however, nonunion is mentioned by several authorities," etc., the implication being that nonunion is now more common than in the past because of treatment by plaster of Paris.

The report of the two cases so successfully treated by the abduction splint is defective because it is not stated whether the fractures were of the intracapsular or extracapsular type. The distinction is important because it has been the accepted belief since the days of Sir Astley Cooper, long antedating the use of plaster of Paris, that intracapsular fractures were incapable of repair, while if one accepts the statement of Dr. Bradford's colleague, Dr. Cotton, all extracapsular fractures unite, irrespective of the character of the treatment. The abduction treatment to which Dr. Bradford probably refers as the plaster of Paris treatment is such, only in the sense that plaster of Paris is used to fix the broken bone after deformity has been corrected and the fragments apposed by distinctive manipulations. Atrophy of muscles and other tissue is an effect of disuse. It is no greater under plaster of Paris than when it is produced by traction, or even by the muscular restraint incidental to acute disease of an unsplinted joint.

Fixation of accurately apposed fragments of a transcervical fracture is absolutely essential to repair because it is an interstitial process unaided by external callus. Fixation for a time is desirable after reduction of the deformity of a fracture at the base in order to prevent excessive callus formation which explains perhaps "the joint stiffness and disability" which, according to Dr. Bradford, "was expected" before plaster of Paris was employed. Muscular atrophy is by comparison an insignificant incident. The point that I would emphasize is that fixation of the transcervical fracture is as essential to repair as it is to bone grafting, and its effect in causing bone atrophy will be the same whether it is attained by a traction splint or by the capsular tension and direct pressure assured by fixation in complete abduction.

Granting all the advantages claimed for the abduction splint its use in the treatment of fracture of the neck of the femur must be limited to the few who can procure the splint and are trained in its application. The abduction treatment by contrast is at the command of any competent surgeon and is effective in assuring the opportunity for functional repair in every type of fracture. It should become, therefore, the treatment of choice and routine, and the reports of results since it has come into general use in this and other countries disprove Dr. Bradford's suggestion that efficient treatment of the fracture is a cause of nonunion.

ROYAL WHITMAN, M.D.

FRACTURE OF FEMUR

EUGENE, OREGON, *March 11, 1925.*

To the Editor:

Thomas J. Maxwell, of Keokuk, Ia., in the early eighties was the first surgeon to use lateral extension, together with direct extension, either from above the knee or including the leg and muscles above the knee. Long strips of *mole* plaster applied on both sides of the thigh and knee, with leg free, or including the leg with plaster or that part with strips of silk, so as to give all extension from thigh and knee. The lateral extension on abduction was made with folds of silk placed on the inside of the thigh, with weight extension according to strength of muscles. The Thomas splint makes use of this same lateral extension without mentioning Thomas J. Maxwell. The article in the MEDICAL JOURNAL AND RECORD of March 4, 1925, by Dr. E. H. Bradford, does not give credit to Thomas J. Maxwell but gives the credit to the Massachusetts Hospital School and gives Dr. Gifford, Dr. Barrett, Dr. Fernald, Dr. Faxon, Dr. Griffin, and Dr. Hammond as references. Dr. Maxwell is dead. The product of his brain in giving the medical profession the lateral extension in fractures of the neck and head of the femur, used in any form of splint, will live forever.

GEORGE O'BRYANT DE BAR, B.S., M.D.

HISTORICAL MEDICINE

LONDON, W. C., *February 13, 1925.*

To the Editor:

Your contributor, Mr. G. Arbour Stephens, of Swansea, Wales, writing of Dr. Haighton's lectures on midwifery, suggests that had he continued his vivisection experiments he might have enunciated the germ theory, the credit for which Mr. Williams ascribes to Dr. E(verard) Maynwaringe, the author of a work on syphilis in 1673. Your contributor proceeds to ask, "Is Maynwaringe an old Guy's student? If so, the hospital can still lay claim to one who, with the words quoted, has been undoubtedly the first to enunciate in unmistakable terms the fundamental idea underlying the modern germ theory." Has your contributor ever heard of Fracastorius? And does he not know that Guy's Hospital was not opened until January, 1725, and that Everard Maynwaringe had then been dead a quarter of a century?

GEORGE C. PEACHEY, L.R.C.P.

10 RANDOLPH CRESCENT.

Book Reviews

HYPERSENSITIVENESS AND TOLERANCE

Infection, Immunity and Inflammation. A Study of the Phenomena of Hypersensitiveness and Tolerance, and Their Relationship to the Clinical Study, Prophylaxis, and Treatment of Disease. By Fraser B. Gurd, B.A., M.D., C.M., F.A.C.S., Montreal, Lecturer in Applied Immunology and in Surgery, McGill University. St. Louis: The V. C. Mosby Company, 1924. Pp. 329.

Although the relationship between hypersensitiveness and other immunological processes is by no means as yet fully determined, enough is already known about the phenomena of tissue hypersensitiveness toward foreign albuminous substances and tolerance (the state in which the tissues are rendered insusceptible to tissue irritation) to make the practising physician and surgeon acquainted with them. Both the hypersensitiveness and the tolerance may exist in the same individual.

Anaphylaxis, the first stage in the immunological reaction, may exceptionally endanger the life of an individual or person, but it also serves a useful purpose in that, as a result of the hypersensitiveness of the tissues to the complex protein molecules which constitute bacteria, the bacterial cell bodies are immediately recognized by the tissue as irritants. The tissues normally respond to irritant substances by focal hyperemia, accumulation of leucocytes, and phagocytosis of the irritant particles.

A proper appreciation of the phenomena of allergy and their relationship to anaphylaxis and tolerance, places the prevention and treatment of infection by bacterial or other protein preparations on a rational basis. Without it the production and control of alterations in the immunological state of an individual becomes, not only difficult, but even dangerous.

Only such matters are discussed as are of practical interest to the clinical practitioner. Only those characteristics of bacteria are studied as determine their pathogenicity and their power to stimulate reactive phenomena on the part of the host. This is probably the first publication to treat the subject matter in this very practical manner. Serology, in so far as it refers to technical methods for the identification of immune bodies, has been excluded. This is the first book on immunology to be written by a practising surgeon, showing that the principles of immunology are finding practical application in surgery.

After a general introduction on the defensive and offensive reactions of the body against irritants and on infection and infectious agents, a study of immunity and immunization is taken up. The general principles of acquired immunity are exemplified by the toxin antitoxin reaction. The term anaphylaxis is fully explained, both as it occurs in animals and in man. The physiology of anaphylactic shock is gone into exhaustively. The nature of transferred anaphylaxis, desensitization, tolerance, anaphylactogen and anaphylactoid phenomena are then discussed. There are various theories regarding the site (humoral or cellular) of the reaction between antigen and anaphylactic antibody. The nature of this reaction is fully explained. It is probable that no matter what the source of the protein antigen may be, the irritating substances so developed are identical in nature. It is therefore believed that it is t physical rather than the chemical characteristics the individual species of bacterium which determi its relative irritative properties, and that consequent induce specific vascular and cellular reactions on t part of the tissues. The function of the leucocyt in immunological processes must also be taken in consideration. Protein-lysin immunity, alexin (cor plement) and sensitizing substance (amboceptor) a the reactions depending on them are then describe Agglutinins and precipitins also have a practical a plication in the treatment of disease. The relatio ship of anaphylactin to other immune bodies is tak up. The hemocellular reaction and the value of t leucocyte count in diagnosis and prognosis are show The focal vascular and cellular reactions to irritan (inflammation) in certain diseases are emphasize Anaphylaxis, as encountered in man, is discusse exhaustively. The chapter dealing with the applic tion of immunity principles to the prevention a treatment of disease is most instructive, as is al that on the therapeutic guidance of the acute inflan matory reaction.

This book may profitably be added to the libra of every practising physician or surgeon.

DIABETES

Manual for Diabetics. By Gladys L. Boyd, M.D. (Tor. Director of Diabetic Clinic, and Clinical Assistant, Hosp tal for Sick Children, Toronto, and Marion D. Stalsmit Dietitian to the Diabetic Hospital for Sick Childre Toronto. Introduction by F. G. Banting, M.D., Ne York: Funk & Wagnalls Company, 1925. Pp. xi-90.

The education of the public in the matter of dia betes mellitus has recently taken the form of diabet manuals, of which many have been published. Wit them it is hoped that the severity of diabetes will b reduced. They help patients to understand their cor dition and to help themselves as well as the phys cian. This book is written in simple language.

The nature of insulin, the technic of its adminis tration and its dangers are described. The selectio and the weighing of food is carefully explained. Th seriousness of the complications of diabetes is em phasized. The technic of uranalysis is explaine About two thirds of the book is concerned with foo values (tables), diabetic recipes and menu planning It may also be profitably placed in the hands of thos who have charge of diabetic patients.

Diabetes. Its Treatment by Insulin and Diet. A Handboo for the Patient. By Orlando H. Petty, B.S., A.M., M.D. F.C.P., Professor of Diseases of Metabolism, Graduat School of Medicine, University of Pennsylvania. Wit Several Illustrations. Philadelphia: F. A. Davis Company 1924.

In the foreword, Dr. John B. Deaver emphasize the necessity of the internist and the surgeon. Th author has shown that "the surgeon, to a great ex tent, must rely on the judgment and experience of th internist, who has made the study of diabetes and it control his own."

The nature of diabetes, its diagnosis, causes an prevention are discussed. The relationship existing between normal blood sugar, renal threshold and

renal glycosuria is well shown. In the study of foods, their proximal principles, inorganic salts and, especially, the vitamines are given special attention. Instructions are given how to weigh and measure foods—which is very important. The method of estimating the food value of diets is well and simply explained, robbing this computation of all its assumed mystery. The estimation of the sugar in urine is explained in detail. Insulin and the method of its administration at home are presented in a very intelligible manner. A large number of sample menus, in which the bulk of the carbohydrate portion varies with the desire of the patient, the protein and fat remaining constant, are given. The food values of the various articles of diet are arranged in tables for ready reference.

THE MIND AND ITS MECHANISMS

Introduction to the Study of the Mind. By William A. White. Nervous and Mental Disease Monograph Series No. 38. Washington: Nervous and Mental Disease Publishing Company, 1924. Pp. 116.

This is one of the most useful books that has appeared in some time. Here we find a modern workable concept of the mind and its mechanisms. White goes back some five hundred thousand years and traces the mind in the making. He then shows the simple everyday workings and the devious pathways which may be taken—and why. He makes clear in his usual lucid manner some of the ordinary bugbear terms, such as identification, displacement, sublimation, projection, symbolization, conversion and many others. It is a book that any intelligent person may read with great benefit. Aside from the wide general interest it contains for the physician there is one chapter every physcian should read carefully—On Bad Thinking in Medicine.

When the physician finishes this interesting book he may well hand it on to his family and friends.

PRACTICAL LECTURE SERIES

Practical Lectures. Delivered under the Auspices of The Medical Society of the County of Kings, Brooklyn, New York. (1923-1924 Series). One Hundred and Thirty-Two Illustrations and Three Color Plates. New York: Paul B. Hoeber, 1925. Pp. xvi-484.

This publication is a new departure in the field of medical literature. Both the Medical Society of the County of Kings, Brooklyn, and the publisher are to be congratulated on this work. This Practical Lecture Series was published for the purpose of giving the general practitioner practical talks on various subjects, rather than formal papers, by teachers interested in special subjects. It is indeed a "valuable addition to the practitioner's working library." The illustrations are very beautiful. The range of subjects discussed covers practically the entire field of medicine and surgery.

Joseph A. Blake discusses The Surgical Abdomen. H. A. Bray writes on An Appraisal of Certain Physical Signs in the Diagnosis of Incipient Pulmonary Tuberculosis. The Treatment of Pneumonia is the work of Harlow Brooks. Appendicitis is discussed by W. F. Campbell. Surgical Diagnosis is assigned to J. B. Deaver and S. P. Reimann. R. L. Dickinson writes about Office Gynecology, which is very complete and instructive. J. Ewing discusses Rational Pathology and the New Therapeutics, emphasizing the value of pathology in the selection of therapy. The Common Skin Diseases are discussed by J. A. Fordyce, giving interesting illustrations and mentioning their treatment. R. S. Fowler writes on Diagnosis of Abdominal Tumors. S. G. Gant gives The Diagnosis and Treatment of the More Common Rectocolonic Diseases. Common Diseases of the Breast are discussed by J. E. Jennings. L. C. Johnson writes about Diabetes and Insulin. E. Libman, an authority on the subject, discusses Subacute Bacterial Endocarditis in the Active and Healing Stages. W. R. MacAusland gives the various causes of Backache. The investigation of The Chronic Diseases of the Joints is described by T. McCrae. H. O. Mosenthal discusses The Value of Tests for Renal Function in the Practical Management of Bright's Disease and Other Conditions. Everyday Bacteriology, the article by W. W. Oliver, describes bacteriological work that may be done by the general practitioner. Dry Labor, The Management of the Breech and Ectopic Gestation are discussed by J. O. Polak. J. C. Regan takes up The Contagious Diseases and Their Treatment. F. Tilney writes about the neurological aspect of Epidemic Encephalitis. Office Orthopedics is discussed by W. Truslow. The article on Medical Psychology by J. J. Walsh is very interesting. The Fundamental Signs in the Examination of Patients, by L. F. Warren, is valuable and illuminating. An index of the articles and authors is also given.

GASTRIC SECRETION

Histoire de la Secretion Gastrique. Par M. Loeper. Paris: Masson et Cie., 1924. Pp. 120.

This little book of Loeper's is a splendid exposition of how we have come to our present knowledge of gastric secretion. It was early suspected that gastric digestion took place as a result of mechanical trituration and by what was for a long time called coction, a process equivalent to simple cooking. As often happens, however, early writers tried to explain the entire process on the basis of one of those factors only, so that much controversy resulted between the proponents of each half truth. It was not until the eighteenth century that the presence of acid was discovered and for the next hundred years not only was the nature of this acid unknown, but it was regarded as a result rather than a cause of gastric digestion. The idea of a glandular secretion of acid juice had yet to be evolved. It remained for our own Dr. Beaumont to lay the basis of the modern conception of the process of gastric digestion and for the Russian Pavlov to produce a proper technic for its experimental demonstration.

The presentation is divided into six periods; the Galenic; the early chemical; the mechanical; the period of acidity (Reamur and Spallanzani); the period of hydrochloric acid and human fistulæ (Beaumont); and the period of pepsin and of experimental fistulæ (Schwann, Claude Bernard and Pavlov).

The book is well illustrated by numerous portraits of the men whose work is described. Incidentally, small as it is, it is perhaps the only individual volume exclusively devoted to a history of any one aspect of gastroenterology. If for no other reason than this it should be on the shelves of every specialist professing a real interest in this department of medicine.

ACCOMMODATION AND REFRACTION

The Errors of Accommodation and Refraction of the Eye and Their Treatment. A Handbook for Students. By Ernest Clarke, M.D., F.R.C.S. Fifth Edition. New York: William Wood and Company, 1924. Pp. i-iv, 1-251.

As an aid to practical refraction this little compact textbook contains in a legible and easily assimilable form practically all that one needs to know about the subject. The author succeeds in covering the entire ground of accommodation and refraction in a practical, terse and concise manner. In marked contrast to the general tendency of European ophthalmologists many of whom are still inclined to belittle the consequences of eyestrain as first elucidated by the American eye men, the author devotes an entire chapter to the subject of eyestrain, especially as related to the nervous system, and takes great pains to impress upon the reader that "the physician who is called upon to treat a socalled functional nervous disorder, and fails to eliminate the element of eyestrain, fails in his duty both to himself and to his patient, as there is no functional trouble that may not be due to eyestrain"—a dictum which though it may appear to some as somewhat farfetched, is in the immense majority of cases very near the truth, and often incontrovertible.

DEVELOPMENTAL ANATOMY

Developmental Anatomy. A Textbook and Laboratory Manual of Embryology. By Leslie Brainerd Arey. With 419 Illustrations. Many in Color. Philadelphia and London: W. B. Saunders Company, 1924. Pp. 433.

This book fulfills its aim. It is a clearly told story of Mammalian intrauterine development. The form of the telling is suitable for the student and avoids the controversial style of many of the more ponderous tomes. For the laboratory, the chick and the pig embryos are described.

DIGESTION AND THE NERVOUS SYSTEM

Essays and Addresses on Digestive and Nervous Diseases and on Addison's Anemia and Asthma. By Arthur F. Hurst, M.A., M.D., Oxon., F.R.C.P. New York: Paul B. Hoeber, Inc., 1924. Pp. 306.

This volume is a collection of reprints on various topics. Hurst writes well and is always interesting. His papers on Addison's anemia and gastric disorders are of particular merit. The contributions to certain of the functional neurosis are stimulating in their attempt to correlate organic changes with functional malfunction.

WORK OF THE ROCKEFELLER INSTITUTE

Studies from the Rockefeller Institute for Medical Research. Volumes XLIX and L. New York, 1924.

These thick volumes contain reprints of papers which have appeared in various journals during the past year from the Rockefeller Institute for Medical Research, most of which have already been abstracted in the MEDICAL JOURNAL AND RECORD. They include investigations of various problems, as in the section from the Hospital of the Rockefeller Institute five of the papers deal with the studies on oxidation and reduction by pneumococcus, and others treat of the pathogenesis of rheumatic fever and its treatment by neocinchopen. The variety of the titles suggests the broad scope of work being carried on in these laboratories.

EPILEPSY

Clinical Studies in Epilepsy By Donald Fraser, M.D F.R.F.P.&S. (Glas.). New York: William Wood an Co.; Edinburgh: E. & S. Livingstone, 1924. Pp. 243.

This book is replete with archaic concepts enter tainingly told. The writer could not make muc progress with the supercilious attitude he takes to ward the psychology of the unconscious. Ancesto worship is more popular in the Orient.

INFANTILE PARALYSIS

Infantile Paralysis in Vermont, 1884-1922. A Memorial t Charles S. Caverly, M.D. Burlington, Vermont: Stat Department of Public Health, 1924. Pp. 375.

This book is a tribute to the splendid work done b Charles S. Caverly in his extensive studies on polio myelitis in Vermont. Aside from the local in terest there are general points of interest in the han dling of the disease *per se.* Many new and salien points on epidemiology are discussed as well as cer tain phases of treatment and prophylaxis which wer inaugurated. There are papers from the many work ers who fought the disease in the State of Vermont

ROMANTICISM

The Green Hat. By Michael Arlen. New York: Georg H. Doran Company, 1924.

If Winter Comes took Main Street by storm. *Th Green Hat* ought to invade Greenwich Village, Par Avenue, and whatever other haunts the *literati* favor It has charm, wit; Arlen tells as romantic a story a anyone could wish. We all love to dream abou great loves, great lovers, and the exquisite Helen o the Green Hat—*pour le sport* is no passive pawn o men's passions.

There is a cult of courageous women in book these days, something between the flapper and th Amazon, riper than the former, mellower than th latter. She appeals to women readers who see i her the tenderness of a great spirited lad, to men wh ache for beauty beyond their eyelids' fall. *The Gree Hat* has a wholly fantastic realism of its own, pos sible yet incredible, an unhappy faroff strain playe in a muted minor key.

To interweave fantasy and fact, to clothe the sor did in sympathy, even to cram sheer beauty into ou busy lives has been Mr. Arlen's successful goal. O rather perhaps he has pleased himself. His reader are also pleased.

A NOVEL

The Eternal Huntress. By Rayner Seelig. New York Alfred A. Knopf, 1924.

After a crude beginning, this novel gathers mo mentum and with it ease until it crashes to a climax with the reader's interest rapt! A wonderful prac tice book for the student of novel construction Every law has been scrupulously observed, and in spite of its constructive values the book has a per sonality of its own. It could be hopelessly trite but it just escapes, it could be dull as only the social stuff can afford to be dull, and it evades the danger neatly. It is certainly not what one could call "a rattling good story." The author still takes himself and his creatures too seriously. But it is pleasing Isabel, sculptress, and her novelist friend are equally lovable, while the curt, older sister and the scheming stupid little adventuress are the necessarily shadowy stepsisters of a Cinderella dream.

Medicoliterary Notes.

A new weekly, *The New Yorker,* has recently made its appearance. Its aim will be to picture metropolitan life a "gay, humorous, satirical" way, yet not to be solely in "a jester." Judging from the first issue, it will deal largely with news of a personal nature about interesting people, and will have an unusually large number of departments and columns, among them, "Of All Things," "Talk of the Town," "Profiles," "The Hour Glass," "The Theatre," "Music," "Books," "Moving Pictures." The staff of advisory editors includes Alexander Woollcott, Ralph Barton, Dorothy Parker, Marc Connelly, Alice Duer Miller, Rea Irvin, and George Kaufman.

* * *

Among addresses of medical interest delivered at the latest annual meeting of the Association of Life Insurance Presidents, held on December 11th and 12th in New York, were the following: Progress of the Warfare Against Disease, by Dr. Oscar H. Rogers, medical director of the New York Life Insurance Company; An Effective Agency for Promoting Periodical Health Examinations, by Dr Franklin H. Martin, chairman of the Board of Directors of the Gorgas Memorial Institute of Tropical and Preventive Medicine at Chicago; and Protect the Individual in the Middle Span of Life, by Dr. Charles H. Mayo, head of the Mayo Clinic at Rochester. Among resolutions adopted was one expressing support of education in the evils of narcotic drug addiction. The proceedings of this meeting have been printed, and include reprints of the above addresses.

* * *

Dr. T. Gilbert Pearson, president of the National Association of Audubon Societies, who sailed recently to attend the coming convention of the International Committee for the Protection of Birds, is quoted as having stated that America leads the movement in saving the birds of the world. Ten and a half million song birds are killed yearly in Belgium alone, and in Italy one of the favorite sports is the netting by the wholesale of small and song birds.

* * *

In the recently issued annual report of the Dean of the School of Medicine of Columbia University there is a note of special interest regarding the organization of a complete series of postgraduate courses which have been carried on in conjunction with the Department of psychiatry. These courses represent the neurological participation in the general plan of the Medical School to offer postgraduate opportunities in all branches of medicine. This is probably the first organized attempt to give a full neurological and psychiatric schedule, so the report says, for postgraduate students in neurology and psychiatry.

* * *

Reports from the Associated Press state that the Soviet Government has recently taken steps to excavate under the towers of the Kremlin in Moscow for the famous hidden library of Ivan the Terrible who lived during the middle of the sixteenth century. This library is reported to contain eight hundred volumes bound in pure gold, and many Arabian, Persian, Assyrian and Byzantine manuscripts and parchments of priceless value. The existence of such a library has been a known fact for centuries, but its exact location has always remained a secret.

* * *

The British press has contained of late a number of editorial tributes to the late Dr. Sigerson, eminent nerve specialist and professor of biology at University College, Dublin. Dr. Sigerson was well known also as a poet, journalist, and historian and a statesman of unusual prominence in the Irish Parliament.

* * *

The latter part of this month a part of the famous Britwell Court Library, formerly the property of S. R. Christie Miller, will be sold at auction in London. It is reported that one of the earliest medical textbooks will go under the hammer at this time. This is *The Treasure of Poor Men,* printed in 1526 by Richard Bankes. As was customary in those days, the subtitle goes on to explain the contents of the work as follows: "Here Begynneth a Newe Boke of Medecynes Intytulyd or Callyd the Treasure of Pore Men, which sheweth many dyuerse good medecines for dyuerse certain dysseases as in the Table of this present boke more playnly shall appere." This is the earliest known edition of this book.

* * *

Dr. Donald B. Armstrong contributes an interesting article to the December issue of *The Nation's Health* on Social Workers and the Health Examination Movement. Dr. Armstrong feels that the extensive national campaign for periodic health examinations now under way is the social worker's great opportunity for putting over ha contribution to public health.

* * *

Two interesting articles on the subject of public health nursing have appeared in the December and January numbers of *The Nation's Health.* The first, entitled A Health Officer's Idea of a Public Health Nurse, is by Dr. John J. Sippy, district health officer of Stockton, California; the second, Definition of a Public Health Nurse, is by Mary Elizabeth Davis, supervising nurse of the Civic Center of San Francisco.

* * *

An editorial note in a recent issue of the *Manchester Guardian Weekly* reports some interesting observations on the effect of a theatrical performance upon an audience in one of the big London mental institutions as made by an actor. One of Pinero's plays was lately given before an audience of a thousand patients. "The chief difference noted between the reception of the comedy by the patients and that by an ordinary audience was that there was constant applause during the performance, and the exit of each player was cheered, not ironically but appreciatively, while at the curtains there was no applause at all. This is of course the exact reverse of what usually happens in a theatre, where interruption point by point would be resented. It might be supposed that the absence of demonstration at the end of the acts was due to an obvious cause,—that the audience did not think it worth while—but this will not do, as there was the greatest enthusiasm at all other times."

* * *

"There are in the United States 40,504 physicians, 191 surgeons, 5,139 apothecaries, 465 chemists, 2,923 dentists, 19 oculists, and 59 patent medicine makers," states *The Dental Monitor* for February, 1885, a Philadelphia publication. According to the *American Medical Directory* there were in 1923 in the United States 145,966 physicians, or one physician approximately to every seven hundred persons.

* * *

Dr. Saxon Pope, of the department of surgery of the University of California, will make one of the party, the other members of which are the author, Stewart Edward White, and Arthur Young, motion picture director, which is to go to British East Africa, where they will hunt lions, tigers, elephants, jaguars, deer and other large game with bows shooting steel barbed arrows.

* * *

The social welfare agencies of Vienna have instituted a "bride's course" to be held in the evenings principally for working girls. This step was taken as a measure for prevention of the many unhappy marriages caused by the modern bride's lack of knowledge of the elementary duties of housekeeping.

* * *

Thomas Jay, the famous writer of *Punch,* recently delivered before the Bristol Rotary Club a Short Discourse on the Alarming spread of Spinal Curvature in Oysters. He complained that, what with historians so minutely describing the past, and Sir Arthur Conan Doyle so clearly foretelling the future, there is nothing left to be uncertain about but the present.

* * *

Only eight minutes are required for New York City ambulances to respond with full medical staff aboard, to emergency calls. This eight minutes covers the time from reception of the call until the ambulance is at full speed. During the year just closed more than 125,000 calls were answered from all of New York's hospitals that provide ambulance service. Acute alcoholism was the cause of the majority of the calls for stricken people, next came insanity, and third pneumonia.—*Report of United Hospital Fund.*

Abstracts from Current Literature

NEUROLOGY

Application to the Cerebrospinal Fluid of the Complement Fixation Test for Gonorrhea in Obscure Cases of Nervous Disease.—F. Green (*Journal of Laboratory and Clinical Medicine,* August, 1924) has made a series of investigations in regard to the reaction of the cerebrospinal fluid to the complement fixation test in cases of gonorrhea, with a number of positive reactions. The following statements are made with regard to the behavior of the cerebrospinal fluid obtained from cases of gonorrhea of the nervous system: Usually the blood serum and cerebrospinal fluid give parallel results, though often the cerebrospinal fluid may give a strong postive complement fixation for gonorrhea, while the same reaction on the blood serum may be negative. The cell count and globulin of the cerebrospinal fluid may remain normal or slightly increased, in spite of a positive complement fixation for gonorrhea, nor does the colloidal gold test of Lange and the colloidal mastic test of Emanuel appear to be affected by a positive reaction for gonorrhea; though in the case of the colloidal gold reaction there may be a slight reduction in the midzone. The study indicates that here is a method by which gonorrhea of the nervous system may be diagnosed.

Treatment of Postencephalitic Parkinson Syndrome with Hyoscine Hydrobromide. — Leslie B. Hohman (*Bulletin of the Johns Hopkins Hospital,* October, 1924) reports on the condition of eighteen patients treated with hyoscine hydrobromide. They were all cases of the Parkinson syndrome following epidemic encephalitis. All showed objective improvement. The maximum amount of the dose was one fiftieth grain four times a day; the average dose was about one one hundredth grain four times a day. It was not necessary to increase the dose because of any acquired tolerance for the drug. Hyoscine proved a valuable palliative remedy in these cases.

Multiple Neuritis, with Korsakoff Syndrome, Following Hyperemesis Gravidarum.—Charles A. Cline (*Medical Clinics of North America,* July, 1924) draws the following conclusions: Toxic multiple neuritis is a frequent sequel of hyperemesis gravidarum. Therapeutic abortion is perhaps too long deferred in many cases of hyperemesis gravidarum, and is the best remedial measure and the most sure means of preventing multiple neuritis. A psychosis of the Korsakoff type is prone to occur in this type of multiple neuritis. The prevention of contractures in the paralyzed limbs is an essential part of the treatment of this condition, and persistent forcible extension will suffice to overcome them should they occur.

Encephalitis Lethargica with Diplopia as an Early Sign.—C. W. Yow (*Lancet,* June 21, 1924) states that in view of the one hundred per cent. of diplopia in his series, encephalitis lethargica should be borne in mind by the general practitioner in every case of "double vision" encountered. Several of his patients consulted their doctors for diplopia, but the real nature of the disease was not suspected. These cases are frequently overlooked in the mild and ambulatory cases unless a systematic inquiry is made into the history.

Postencephalitic Behavior Disturbance Without Physical Signs.—Bert I. Beverly and Mandel Sherman (*American Journal of Diseases of Children,* June, 1924) maintain that even in the absence of definite neurological findings or a history of an acute disease, or both, when a child shows a sudden change of personality and symptoms of impulsive delinquencies and childish mannerisms, the appearance of deterioration in contrast with a high mental test rating, explosive reaction, with general hyperkinesis and irritability, or marked indifference with sluggish physical reactions, the possibility of an organic brain disease, especially postencephalitis, should be considered.

Backache; Unilateral Sacralization of the Fifth Lumbar Vertebra.—Heinrich Martius (*Zentralblatt für Gynäkologie,* July 19, 1924) calls attention to an unusual and peculiar cause for a persistent form of backache—that due to unilateral sacralization of the fifth lumbar vertebra. The modern theory of constitution correctly attributes pains in the back very frequently to asthenia, especially in the presence of musculature that is easily exhausted, in which case the seat of the pain is attributed to the musculature itself by some and to the vegetative nervous system by others. However, local causes, especially the more latent factors must be taken into consideration. As an example of such a cause the author cites the case of an assimilation between the last lumbar and the first sacral vertebræ. The treatment includes diathermy, faradization and röntgen irradiation directed against the secondary inflammation. Surgical intervention has also given good results, but this procedure is associated with great difficulties.

Migraine.—Arthur F. Hurst (*Lancet,* July 5, 1924) nearly always obtained considerable improvement and frequently complete cures in his cases of migraine since he thoroughly examined his patients for ocular defects in addition to giving the usual medicinal and general treatment. He found that hyperopic astigmatism, especially when associated with latent hyperopia, is the most common error of refraction encountered. Astigmatism, which is generally compound, is very rarely entirely absent. Very small errors are quite sufficient to give rise to migraine, especially in highly strung, clever people with an irritable migraine storm centre. For this reason the most accurate possible correction of every error is required.

Phosphate Ratio in Mental Disease.—William Moodie and Eileen A. Boyd (*Lancet,* August 2, 1924) draw three main conclusions from an analysis of their results: 1. There is a definite type of confusional insanity which always shows the socalled acidosis reaction. This occurs at all ages and the prognosis is usually good. 2. The numerical value of the phosphate ratio remains constant in each case during the confused period. 3. An acidosis reaction is not uncommon in excited states, but this does not apply to manic depressives. The phosphate ratio may, therefore, prove to be a valuable aid to prognosis. Several methods of combating the acidosis as a therapeutic measure have been devised, but it is, as yet, too early to express any definite opinion as to their efficacy.

Compression Paraplegia and Pott's Disease.—C. Wallace (*Journal of Bone and Joint Surgery,* July, 1924) draws the following conclusions from his study of numerous hospital cases. Paralysis rarely developed when the focus of disease was below the tenth dorsal vertebra or when efficient orthopedic treatment and care had been administered. The Calot plaster of Paris jacket with pressure pad of plaster of Paris bandage and cotton, or Bennett's felt pressure block offers the best and surest method of a cure of the paralysis as well as the greatest promise to cut short its duration and reduce the deformity. The improved method of the treatment of Pott's disease and its early diagnosis have acted as a control in preventing the paralysis. There has been manifested a decrease in the occurrence of Pott's disease, which might warrant one in inferring that other forms of bone tuberculosis have correspondingly diminished in New York. A complete eradication of this infection may not be expected but the minimum appearance of this deforming disease is being rapidly approached. The author believes that this is accounted for either through the therapeutic and prophylactic programs as carried on by the various health and philanthropic organizations or by having the child's resistance to this disease raised to a maximum through the numerous activities of child welfare organizations.

Thrombosis of the Cerebral Sinuses Following Pneumonia and Other Morbid Conditions.—W. G. Wyllie (*British Journal of Children's Diseases,* April-June, 1924) states that sinus thrombosis is seldom recognized clinically except in those cases which are of otitic origin. This is due to the fact that its symptomatology is common to other conditions which are more frequently met with, such as meningitis and cerebral abscess. The diagnosis may be aided by an examination of the cerebrospinal fluid. It is almost certain that sinus thrombosis may arise from causes other than inflammatory. The strongest evidence in support of this theory is the possible occurrence of thrombosis of the sinuses in cases of chlorosis. Factors operating to bring about such a result are an altered state of the blood, weakness of the heart, and degenerative changes in the intima of the bloodvessels. Cases secondary to middle ear disease are amenable to surgical treatment. Recovery in any other type of cases is of exceptionally rare occurrence.

Backache from Vertebral Anomaly.—T. A. Willis (*Surgery, Gynecology and Obstetrics,* May, 1924) presents the following summary of his findings. Though the human spinal column is the most stable of the primate columns, it still presents frequent variations from the normal type. These variations result from an evolutionary shortening of the column by cephalad progression of the pelvic girdle complex upon the column. The articulation of the girdle with the column is, therefore, a region of morphological instability as evidenced by the frequent occurrence of development anomalies. Spinal columns thus affected are predisposed to mechanical derangement the symptoms of which are essentially ligamentous in origin. The anomalies may be divided into two groups, one of which involves the last lumbar segment alone and the other the articulation between this segment and the first sacral. The former includes various types of interruption in continuity of the neural arch, and the atypical transverse process. The defect of the arch is responsible for the occurrence of spondylolisthesis and kindred disorders. The latter group comprises the abmodal developmental formations of the articular processes. Each group gives rise to definite clinical syndromes. The form of treatment and prognosis depend upon the individual case.

Minor Injuries of the Brain.—Wilfred Trotter (*Lancet,* May 10, 1924) believes that, just as with other viscera that are inclosed in serious membranes, the most effective stimulus producing pain is stretching. Alterations in intracranial pressure and inequalities in its distribution as a result of the arrangement of the septa of the dura produce alterations in tension. Headache of organic origin is the result of disturbances of the intracranial pressure. The reduction of intracranial pressure is rarely the cause of headache. Owing to the arrangement of the dural septa, a local reduction may produce painful stretching until the pressure has become equalized, as occurs in cases of headache following lumbar puncture and the withdrawal of spinal fluid. If the disturbance of intracranial pressure is severe or rapidly progressive the headache is continuous with moderate disturbance, or if it is stationary or slowly progressive, the headache is paroxysmal, as in cases of some slowly growing tumors early in their development and characteristically in traumatic headache. When the headache follows an injury and resulting concussion, the brain is edematous. If the headache follows a localized blow on the head the brain shows localized bruising when exposed.

Surgical Repair of Peripheral Nerves.—H. Delageniere (*Surgery, Gynecology and Obstetrics,* November, 1924) offers his study of three hundred and seventy-five cases, and points out that the earlier the suture is performed the more rapid is the regeneration. The correctness of this statement is proved in the case of causalgia treated by resection followed by immediate suture and in the case of suture made at the time of injury. In the case of delayed suture, the regeneration is simply delayed, but eventually it should be just as complete. The author says that complete and excellent results have been obtained in the case of a suture performed as late as twenty-eight months after the injury. No matter how old the wound, it is worth the trial of operation. The regeneration appeared to be much quicker when there was complete physiological interruption but no separation of the ends of the nerve. With the separation of the two ends, regeneration is less rapid, just as in the case where the peripheral segment was very markedly disorganized.

The radial, musculocutaneous, and external popliteal nerves regenerate most quickly. The internal popliteal, the ulnar, and the median regenerate with greater difficulty. This is due to the fact that there is a greater number of sensory fibres which go to make up the nerve and to the danger of aberration of the nerve fibres in the new formation. The motor fibres grow down into the open sheaths of the sensory fibres, and vice versa. This produces a type of useless regeneration.

The suture must be done in a simple manner using very thin straight or small curved intestinal needles. Use very fine silk. In making the suture avoid transfixing the nerve, the stitches are put through the nerve sheath without touching the nerve itself. The main effect of this suture is to approximate the ends and at the same time to prevent any overlapping. As this suture is made to hold in slight tension, catgut should never be used because it may absorb before the fusion of nerve elements occurs. Physiologists have shown that the union of a sutured nerve occurs soon, but is not firm until after four weeks. After this period a sutured nerve cannot be torn off by the normal motions of limbs, even if it was sutured in flexion, and there is no danger in putting the limb through gradual progressive movements of extension.

In order that the different bundles correspond with each other at both ends, it is best to establish a landmark. Thus one stitch is made in the posterior middle part and the needle perforates the neurilemma about two millimetres deep. Two more stitches are inserted so that the first will be in the median line. Then the first one should be tied. The nerve is then allowed to assume its normal position, so that both ends come together. The suture may be completed with two or three more interrupted sutures.

1. In grafting, dissect the musculocutaneous nerve in a length double that needed in the graft. 2. Divide the nerve in two pieces of equal length. 3. Transfix these two ribbons with fine silk. 4. Suture the graft in such a manner that its ends fit like parts of the nerve. 5. Do not tie the sutures too tightly.

Spontaneous Subarachnoid Hemorrhage. — C. P. Symonds (*Quarterly Journal of Medicine,* October, 1924) treats of the clinical and pathological aspects of spontaneous subarachnoid hemorrhage from a study of 124 cases found in the literature, and places on record three new cases of his own, discussing the anatomical pathways by which blood may gain access to the subarachnoid space. The differential diagnosis and treatment are described, as are some of the various hypotheses which have been advanced to account for this condition. The author believes that intracranial aneurysms are a more common cause of spontaneous subarachnoid hemorrhage in young people than is generally supposed.

Treatment of Spasmodic Torticollis.—K. G. McKenzie (*Surgery, Gynecology and Obstetrics,* July, 1924) reports a case in which operation was performed by Dr. Harvey Cushing, of which he says: Intrameningeal division of the right spinal accessory, together with the combined trunk for each of the three upper right cervical segments was performed. Great improvement followed the operation. Intraspinal division of the posterior roots only of the upper cervical nerves, leaving the anterior roots intact, is suggested. It is thought that by this means the spasm in the posterior muscles, as seen in torticollis, could be markedly diminished, if it could not be entirely abolished, and that the weak active function of these muscles would still be retained.

Regeneration of the Meninges.—M. Lear and S. C. Harvey (*Annals of Surgery,* October, 1924) deduce from their experiments that the lining cells of the piaarachnoid are more highly differentiated than those of the dura and therefore are more stable in character. The lining cells of the dura are mesothelium derived from the mesenchyme, are less stable and readily enter into any adjacent inflammatory action. When destroyed they are replaced by the transposition of mesenchymal elements into mesothelium. The inner surface of the dura does not act as a limiting membrane in the presence of an attempted repair in the underlying meninges, but on the contrary enters intimately into the process. Consequently the piaarachnoid when injured becomes adherent to the dura, and heals with adhesions.

Treatment of Brain Abscess.—J. E. J. King (*Surgery, Gynecology and Obstetrics,* November, 1924) thinks that various operative procedures heretofore described, in which numerous kinds of drainage materials were used, have usually been followed by a high mortality rate. In all of these procedures described, prevention of hernia cerebri has been desired. The author advises the creation of a rather large cranial defect directly over abscess cavity; complete "unroofing" of cavity; complete herniation or eversion of cavity; prevention of trauma and early compression of hernia cerebri; adhesive plaster strapping; epithelialization.

Rigidity of Striated Muscle in Spastic Paralysis.—J. I. Hunter (*Surgery, Gynecology and Obstetrics,* December, 1924) emphasizes his belief that the basic principle of the operation of sympathetic ramisection is that it removes plastic tone. It is indicated only when plastic tone is in excess and hampers the voluntary activities which have persisted in spite of the central lesion. A study of the nature of the spasticity of the spastic limbs, and an estimate of the anatomical defect of the central mechanism responsible for the condition, must go hand in hand, and only when the physiological indications are discoverable is the operation to be undertaken.

Treatment of Spastic Paralysis by Sympathetic Ramisection.—N. D. Royle (*Surgery, Gynecology and Obstetrics,* December, 1924) following up experiments on animals to determine the function of the sympathetic nerves, now performs the operation on humans with encouraging success. The operative technic of lumbar sympathetic ramisection, abdominal sympathetic ramisection, and cervical ramisection are given, and the results which the author has achieved in his own numerous cases.

Cerebellar Abscess of Otitic Origin.—W. P. Eagleton (*Surgery, Gynecology and Obstetrics,* November, 1924) enumerates the objections, as he sees them, of both the ordinary operative treatment and Bourget's operative treatment of this complication. In their place he submits a technic of his own, which, with his comment upon it, follows. The operation is begun by uncovering the dura over both cerebellar hemispheres, followed by an exposure of a lateral sinus of the affected side. A clean area is obtained by approaching the sinus from behind after which the sinus is obliterated by the invulsion of its outer wall into its cavity, just below the knee; and by an encircling ligature in its lower portion. This procedure will admit of a free incision of the dura through the walls of the sinus, with enlargement anteriorly or posteriorly into the contiguous dura surface, and this in many cases in an uninfected area. The author says that his experience with this method is still too limited to warrant the statement that the mortality from cerebellar abscess will be improved by its adoption, but he believes that theoretical considerations and the high mortality from other methods certainly justify its trial in suspected cerebrellar abscess especially during the socalled latent period, when a positive diagnosis of cerebellar abscess is impossible and when consequently exploration by the recognized methods may not be warranted because of the risk of infection of the meninges.

Headaches of Intranasal Origin.—A. W. Greene (*International Journal of Medicine and Surgery,* October, 1924) considers the variety of pressure points that may cause headache. Severe and sometimes constant headaches may be caused by the mere pressure of an inferior turbinate on a septum, though the more common form is produced by pressure between the middle turbinate and the septum, either from hypertrophy or engorgement of the former or deflection of the latter, or both. There are socalled reflex spots in the nose, apparently more sensitive in the female. These areas hypertrophy during the menstrual period, and should there be an already decreased space, the result is not infrequently headache. Dysmenorrhea has been relieved by cocainizing these areas.

Turning our attention to the middle turbinate alone we can have a hypertrophy or malposition which causes a pressure on the lateral wall. The pressure alone can produce pain, referred through Meckel's ganglion or to the ophthalmic, but more frequently the headache is due to a blocking of the frontal sinus and anterior ethmoid cells. Hypertrophy and malposition have less to do with involvement of the posterior ethmoids, except indirectly—in other words, the headache is rarely from direct pressure of the turbinates. It is more the congestion or pus pressure due to improper drainage induced by hypertrophy or malposition. The anterior and posterior ethmoids may be separately involved, but more frequently are jointly affected. This pain is between and in the eyes, at the vertex, and there is danger of optic nerve involvement. Going back to the sphenoids, headache only results from congestion, hyperplasis, pus and negative pressure. Malposition plays no part and pressure between the turbinates and septum is not a factor (except causative for the sinusitis). The most confusing is the frontal headache of sphenoid origin—probably due to direct pressure on, or toxic envolvement of, the first division of the fifth, or even the semilunar ganglion itself.

The diagnosis is made by careful history taking, inspection (direct and indirect), aided by transillumination, x ray and cocainization. The latter not only dulls the pain, but shrinks tissue, thus aiding inspection.

The treatment, of course, depends on the diagnosis, which can only be arrived at after long and painstaking differentiation. Each point of pressure must be relieved, if possible, temporarily, so that we may determine whether permanent removal of such pressure will or will not cure.

Depletion of turgescent tissue will very often reduce points of pressure, so that no operative removal will be necessary.

MALIGNANCIES

Cancer of the Cervix.—Sidney Forsdike (*British Medical Journal,* July 19, 1924) draws the following conclusions:

1. That for cases of carcinoma clinically limited to the cervix the only treatment is operative.

2. That for cases which have clinically invaded the peri-cervical tissues the treatment is by radium to the cervix and x rays to the pelvic tissues.

3. That salts of copper play an important though subsidiary part in the treatment by radium.

4. That preoperative and postoperative irradiation is of considerable value.

Melanoma of the Nail Bed.—T. Banford Jones (*Annals of Surgery,* December, 1924) summarizes his findings as follows. Melanoma of the nail bed resembles paronychia, but is chronic and shows pigmentation. Occasional cases may occur without obvious pigmentation. The diagnosis is ordinarily made late with the result that treatment is hopeless. This condition must be considered in all chronic conditions of the nail bed. Diagnosis should be confirmed by excision and microscopic examination of tissue, followed by immediate operation

Significance of Blood Nitrogen in Cancer.—B. S. Barringer and R. Theis (*Surgery, Gynecology and Obstetrics,* October, 1924) assert from a number of cases of prostatic and bladder carcinoma that a high urea nitrogen definitely indicates that the kidneys may not stand the strain of operation.

Physical Diagnosis of Carcinoma in the Bronchus of the Upper Lobe.—Wilhelm Neumann (*Wiener klinische Wochenschrift,* May 1, 1924) states that percussion in the presence of carcinoma in the upper lobe bronchus reveals a normal apex with almost absolute dulness in the median half of the infraclavicular fossa down to the third rib and beyond the farther edge of the manubrium. Auscultation reveals absence of bronchial breathing, amphoric sounds or râles and diminution or absence of vesicular breathing. In this way a practically important differential diagnosis can be made in many cases.

Carcinoma of Prostate.—Gordon S. Foulds (*Canadian Practitioner,* November, 1924) arrives at the following conclusions: Carcinoma of the prostate occurs approximately once in every five cases of prostatic obstruction. Metastasis is common in carcinoma of the prostate. One third of the patients have metastasis when they consult a surgeon. Osseous metastasis occurs most frequently in the pelvic bones, spine and femurs. Roentgen ray examination of these parts should be made routinely in all cases before treatment is begun. Prostatectomy is indicated in early cases. Radium therapy is of value, but is only indicated in about half the patients presenting themselves with this disease. Thorough irradiation of all parts of the gland with moderate doses, applied throughout the whole gland, should be aimed at, rather than heavier irradiation less well distributed. Prolongation of life can be expected in only one fourth of the patients treated—though symptomatic relief may be expected in seventy-five per cent. of cases.

Operative Treatment in Cancer of the Uterine Cervix.—J. L. Faure (*Bulletin de l'Académie de médecine,* October 21, 1924) reports steadily improving results in abdominal hysterectomy for cancer of the cervix. Up to 1906 he had operated on twenty-five patients, eighteen of whom had survived the operation and twelve were traced and found living in 1906; at least two of these are still living. Later statistics dealt with eighty-three private cases, among which the operative mortality was 10.84 per cent. The percentage of lasting recoveries in this series was 52.12 per cent.; even among the thirty-six worst cases, lasting recoveries amounted to 27.58 per cent., while among the eighteen favorable, early cases they amounted to 88.23 per cent. The operative mortality was still high, however, being about twenty per cent. among hospital cases. In the last three years, realizing that this mortality was due almost entirely to infection, the writer has treated all cases as if they were severely infected, using Mikulicz drainage as a routine. This promptly reduced the mortality to two out of seventy-five cases, or less than three per cent. Extensive hysterectomy for cervical cancer can thus now be stated to be no more dangerous than simple hysterectomy for annexitis or fibroids. Radium, while of great service in inoperable cases, has yet to show such results in the operable cases as are now obtainable by operation.

Late Recurrence of Carcinoma of Breast.—G. Woolsey (*Annals of Surgery,* December, 1924) asserts that there is no time limit to the occurrence of recurrences. Recurrence is the rule and not the exception, but the ratio decreases in proportion to the time after operation. Irrespective of the time they appear after operation, local, regionary and metastatic growths are recurrences in the great majority of cases. Permeation of the fascial lymphatics accounts for most of the recurrences in the other breast and locally. The only way of lessening these is by early operation, wide removal of the deep fascia and postoperative radiation. Early radical operation, before the glands are involved, is still the best treatment, gives the best late results and avoids most cases of recurrence. The x ray, with or without operation, is the best treatment of recurrent cases and one of the best means of preventing postoperative recurrence.

The Relative Value of X Rays in Various Forms of Malignant Disease.—Francis Hernaman-Johnson (*Practitioner,* November, 1924) thus sums up his observations. Carcinoma is amenable to x ray treatment in the following order: breast, pelvis, stomach, esophagus, throat. Most sarcomata are readily affected, so far as the primary manifestations are concerned, but the expectation of life is not increased.

Both the divided dose and the intensive method have a legitimate place in treatment: the former for use in conjunction with surgery and as a prophylactic after operation; the latter in selected cases when surgical procedures have failed, or are not contemplated.

The results of intensive x ray treatment in severe, inoperable, or recurrent carcinoma of the breast or pelvis are often so brilliant that for some months, or even years, the patient may feel and appear normal. This temporary resurrection is in itself an end well worth seeking, and no wave of pessimism should be allowed to prevent patients from having the chance to attain it. Radiotherapy has made steady progress during the past few years.

A second intensive course occasionally repeats the good effects of the first, but a third rarely does so. The problem to be solved is how to make the benefits of successive courses cumulative. In so far as failure may be due to an immunity to x ray action possessed by later recurrences, the author believes we have at present no hint as to how to deal with the matter, but as regards maintaining in the patient himself the power to respond, we are in a better position. For we know that good surroundings, a diet rich in vitamines, and synthetic sunlight are capable of stimulating the body's resistance to disease; and they have not, so far, been used in any systematic way as aids in the fight against cancer.

Biological Aspects of the Radiation Therapy of Cancer.—Claude Regaud (*Canadian Practitioner,* September, 1924) says that there really exists, not only between different organs, between different tissues of the same organ, between different cell types of the same tissue, but also between the different physiological phases of the same cellular species, differences in radiosensitivity, and presents the following conclusions:

1. The radiation treatment of cancer must make use of the selective action of the rays in preference to their diffuse caustic effect.

2. The required selective action calls for more penetrating x rays, for increased voltages and higher potential tubes.

3. Radium therapy must employ ultrapenetrating gamma rays, filtered by heavy metals, as recommended by Dominici in 1907. The tube method is good, but not because it brings in the beta rays. It is inferior to the radium puncture method, with ultrapenetrating gamma rays. This last technic has the advantage of reducing the diffused caustic effect, the serious afterreactions, and radionecrosis.

4. The decreasing radiosusceptibility of the cancer cells treated by small, ineffective and successive doses, imposes the necessity of the single continuous or discontinuous treatment.

5. The chronological distribution of this single complete treatment must be adapted to the life peculiarities of the cancerous tissue.

Generally, the treatment is more effective if continuous and extended over six to ten days. This is particularly true for the epidermoid squamous cell cancers. The röntgenotherapy of cancer will also undoubtedly benefit in following as much as possible all these rules.

Radium in Prostatic Carcinoma.—B. S. Barringer (*Annals of Surgery,* December 1924) submits that the best method of treatment in our hands has been by radium needles inserted into the prostate and seminal vesicles, this repeated every two or three months until sclerosis of the carcinoma occurs. If there is urethral invasion, urethral treatment is added to the needle treatment. In from five to ten per cent. of cases, the carcinoma ought to be controlled by radium. Bone metastases occur in our cases in twenty-seven per cent. The diagnostic needle developed at the Memorial Hospital enables us to make an accurate diagnosis in a much larger percentage of early cases, and is used routinely in the diagnoses in question.

Simple and Malignant Tumors of the Breast.—Jane C. MacDonald (*Glasgow Medical Journal,* July, 1924) summarizes a long clinical and pathological study thus: The cases generally seen in hospital fall definitely into the three groups of mastitis, simple tumor, and malignancy. The malignant cases are sufficiently well developed when they present themselves to be easily diagnosed. In the early cases the doctor is not, as a rule, consulted, and only occasionally is he responsible for delay. There are practically no definite signs to indicate malignancy in its very early stages, and the plea for early recognition amounts to the careful examination, consideration, and interpretation of the individual case. The question of the education of the public as to the early recognition and treatment of cancer has its drawbacks, as the fear of malignancy in the mind of the patient or practitioner may lead to the unnecessary removal of a number of breasts. More conservative methods seem to be more in accordance with the pathological conditions.

Fibroid Tumors Complicating Pregnancy, Labor and the Puerperium.—Trevor B. Davies (*Clinical Journal,* July 16, 1924) says that the dangers of fibroids complicating pregnancy have been greatly exaggerated. The great majority of cases require no treatment. If the tumors become painful during pregnancy, rest, anodynes and mild aperients are indicated. Interference during pregnancy may be necessary under the following circumstances: Twisting of pedicle of subperitoneal fibroid; degenerative changes causing rapid enlargement of the tumor; extreme dypnea or distention of the abdomen, and severe hemorrhage. Myomectomy or hysterectomy will be required in these cases. The former is indicated if the fibroid is isolated, subperitoneal, or has a twisted pedicle. Hysterectomy is indicated if the fibroids are multiple or if the bleeding during a myomectomy cannot be controlled. Abortion often follows myomectomy. During labor careful watch and examination of the patient will enable one to determine whether a fibroid will obstruct delivery or not. If the obstruction does not become relieved by the tumor rising up into the abdomen, then operation is indicated as in the case described. Cæsarean section followed by total hysterectomy is the operation of choice. Total hysterectomy is just as easy as the subtotal in these cases, and in cases of doubtful asepsis is undoubtedly the better of the two. In the puerperium a polypus should be removed *per vaginam.* In infected subperitoneal or interstitial tumors total hysterectomy should be performed.

Carcinoma of the Breast.—B. J. Lee and N. W. Cornell (*Annals of Surgery,* September, 1924) present the following report of eighty-seven primary operable cases admitted to the New York Hospital prior to April 1, 1919.

1. Five year results in the treatment of mammary cancer are the shortest ones worthy of report.

2. The five year results in this series show fifteen per cent. of the patients alive and with no evidence of disease.

3. The term cured should be abolished and supplanted by "no evidence of disease to date."

4. Criteria of operability must be more sharply drawn.

5. The surgeon must learn to appreciate the physical and radiographic signs of early chest metastasis.

6. Metastasis to bones must be carefully excluded in every presumably primary operable case.

7. Continual followup of all postoperative cases is necessary if correct figures are to be obtained.

8. The term carcinoma of the breast probably includes a group of diseases differing in their pathology and their degree of malignancy.

9. Unusual pathological types should be collected in order that they may be separated out, the nonmalignant from the truly cancerous.

10. In cases with involvement of axillary nodes, radical amputation usually yields disappointing end results.

Medicolegal Notes.

FACIAL SURGICAL OPERATION AS A "REASONABLE AND NECESSARY SERVICE OF A PHYSICIAN" UNDER THE CONNECTICUT STATUTE

In an action by a physician and surgeon against a husband and wife for the agreed on compensation for performing an operation on a scar on the husband's face, extending from the mouth to the ear, which operation greatly improved the patient's personal appearance, the question was raised whether the wife was liable under Connecticut Gen. Stat. 1918, §5275, providing that both husband and wife "shall be liable for the reasonable and necessary services of a physician rendered the husband, wife or their minor child."

Affirming a judgment for the plaintiff as against the husband and in favor of the wife, the Connecticut Supreme Court of Errors said, Ematrudo v. Gordon, 123 Att. 14, that the service rendered must be both reasonable and necessary. "In any given case it might well be that the station in life of the parties, their usual style of living, and their pecuniary position in general, being upon a liberal and generous scale, would justify charging the wife with the services of a most expert and expensive practitioner of plastic surgery to restore the husband's facial symmetry and comeliness; on the other hand, on account of facts of the same nature, but compelling a contracted mode of life and careful attention to pecuniary outgo, and considering the requirements of a less exacting social environment, it would be unreasonable and unjust to compel a wife, not by reason of her own contract, but as a burden cast on her by statute, to defray a charge such as that just suggested, or indeed any charge. To determine the question the trier would have to consider in the instant case what was the extent of the family income, the nature of the husband's employment, and whether it was steady or casual, whether or not the appearance of his face after the accident and prior to the operation, which interval the trial court states to have been a long time, had in fact operated adversely to the continuance or procurement of employment. There was also to be considered the extent to which both husband and wife contributed to the family support, the existence of any invested property, and in general the pecuniary situation of the parties and their social surroundings and general course of life. It is found by the court that there was no pain or suffering caused by the injury resulting in the scar.

"Assuming that the trial court had found facts showing that the station in life, style of living, and pecuniary situation of this family would have made this expenditure reasonable and necessary the conclusion of the trial court upon such a state of facts that these services were neither reasonable nor necessary would have been reviewable as a matter of law, and error must have been predicated thereon. But without these additional facts the conclusion of the trial judge must be tested as a matter of law upon the facts found, and upon these we must conclude that the trial judge was not in error in drawing the conclusion which he had drawn."

NEGLIGENCE IN FACIAL OPERATION

In an action in tort for malpractice in the performance of a surgical operation upon a thin lip, the California Supreme Court, Hall v. Steele, 226 Pac. 854, says: "In such cases whatever representations the physician, surgeon, or dermatologist may have made as an inducement to the performance of the operation are not essential to the plaintiff's alleged cause of action for negligence; the sole actionable issue being as to whether or not the operation was skillfully or unskillfully performed. In an ordinary action for malpractice the physician or surgeon is not to be held as a warrantor of cures or of consequences other than those arising from a breach of his duty to perform the operation skillfully, and if, as the individual cases show, through no unskillfulness on the part of the surgeon, the plaintiff's broken arm was permanently impaired (Houghton v. Dickson, 29 Cal. App. 321; McGraw v. Kerr, 23 Colo. App. 163), or the patient's nervous system shattered (Booth v. Andrus, 91 Neb. 810), or if the patient fails to recover (Wardemann v. Barnes, 92 Wis. 206) or even if, as in this case, the facial expression of the plaintiff is altered to an extent amounting to a disfiguration, the plaintiff cannot recover in this form of action without being able to show that the specific operation which the surgeon was engaged to perform was negligently and unskillfully performed."

The question whether these principles apply to naturopaths or "beauty doctors" did not arise in the case, the pleadings sounding in tort and being based on an alleged unskillful surgical operation. The court said a different issue involving this question would have been presented if the action had been one for the breach of warranty as to the result of the operation performed. Another question which was not discussed in counsels' briefs and which was therefore not decided by the court was as to the defenses which are available to a naturopath who undertakes to perform a surgical operation which his license as such naturopath does not entitle the holder to perform.

It was held that the expert evidence warranted the verdict of the jury that the operation performed was not the suitable one from a surgical point of view to accomplish the result desired and attempted, of narrowing the plaintiff's mouth, and judgment for plaintiff was affirmed.

REVOCATION OF LICENSE FOR CONVICTION OF CRIME INVOLVING MORAL TURPITUDE

The Georgia Supreme Court holds, Hughes v. State Board of Medical Examiners, 123 S. E. 879, that a court of equity will not enjoin the State Board of Medical Examiners from hearing a proceeding brought under section 14 of the act of August 20, 1918 (Acts 1918, p. 173), for the revocation of the license of a physician upon charges that he had been convicted of a crime involving moral turpitude and had caused the publication and circulation of an advertisement relative to diseases of the sexual organs, the grounds on which such injunction was sought being, first, that said section of said act was unconstitutional and void for certain designated reasons; second, that the provision making "conviction of crime involving moral turpitude," and the provision making "the publication and circulation of an advertisement relative to any disease of the sexual organs" are so vague, uncertain and definite as to render them void; third, that he had been granted a full pardon for the crime for which the revocation of his license was sought; and, fourth, that the defendants, unless restrained, would revoke his license and thus deprive him of the right to practise his profession, which was a valuable property right, as the plaintiff had adequate and complete remedies at law, by which, in the first instance, he could set up the alleged matters of defense before said board, and in the second instance, by an appeal from any judgment of said board, if adverse to him, to the superior court of the county of his residence, where all such matters of defense could be set up and determined. Such a proceeding was held to be quasi criminal in character, and within the general rule that a court of equity will not enjoin prosecutions for criminal offences or quasi criminal proceedings.

Important Ophthalmic Signs in Diseases of the Nervous System

J. PAUL DE RIVER, M.D.
San Francisco, California

One of the most important adjuncts to the diagnosis of diseases of the brain and central nervous system is through the medium of the eye, and for many years these ophthalmological manifestations have occupied a prominent place in medical science. Appreciating the immense importance of this vital subject, the ophthalmologist and the neurologist have devoted much time and study to it, that they might speak with some definite assurance on the subject.

If we but consider the close relation existing between the eye and the brain; the retina being an outgrowth from the rudimentary brain of the primary optic vesicle, and (1) the optic nerves being portions of the lobes of the brain, one may readily understand how the early manifestations of diseases of this organ may reveal themselves through the eye. The ophthalmologist is able, in many cases, upon examining the eye, to recognize pathological changes in their incipiency, and therefore make an intelligent diagnosis before the disease has progressed beyond the aid of medical or surgical intervention.

Assuming that the eye is a portion of the brain, then disease of this complex machine will, in many instances, reveal early changes in the visual organs by an alteration in the normal physiological functions, which manifest themselves by organic changes in the anatomical structure of the eye and visual pathway; or by functional derangement of its mechanism.

At this writing, I do not propose to go deeply into the study of any particular disease; the variegated symptomatology and diversity of syndromes would carry one far into other fields. I will, therefore, limit myself to the discussion of a few of the most common diseases of the nervous system, and attempt to give the eye signs encountered in each, with an outline for examination that I have found useful (2). This method of examination, if followed carefully, will enable one, upon correlation of the findings, to make a satisfactory diagnosis. Etiological and pathological changes that ensue, will not be discussed in detail, but merely touched upon when necessary. The following outline is of particular value:

1. Sensibility of the cornea.
2. Size, shape and reaction of the pupils.
3. Abnormalities of extraocular muscles; squint, nystagmus or paralysis.
4. Visual acuity, near and distant.
5. Visual fields.
6. Examination of fundi, noting condition of optic disc as regards atrophy, edema, or alterations in the bloodvessels.
7. Abnormalities, such as exophthalmos, ptosis of lids, inflammation, operations, or injuries.
8. To this list might be added convergence reaction, especially noting any possible paralysis of convergence or divergence.

Corneal sensibility is tested by gently touching the cornea with a piece of absorbent cotton twisted to a thread, noting the discomfort experienced by the patient and the rapidity with which he blinked; this test reveals any loss of function in the ophthalmic division of the fifth nerve. If winking reaction is slow or absent, we immediately think of the following:

a. Section of this branch.
b. Herpes zoster involving this branch.
c. The use of some drug in the eye, as cocaine.

If sensibility is diminished and unilateral, without facial hyperesthesia, it may mean tumor of the cerebellum on the same side. In this case, we should look for an accompanying nystagmus which is of the coarse type and to the same side, an unstable gait and a tendency to fall to the same side.

Hysteria.—This condition may cause hyperesthesia of one or both corneas, with accompanying sensory disturbances of other parts of the body, often with equal pupils and negative fundus findings.

Size and reaction of pupils.—Inequality of pupils is always pathological. Contraction of pupils takes place through the third nerve; dilatation through the sympathetic ciliospinal centre. The average pupil should measure about four mm. in diameter, allowing for old age, at which time the diameter is diminished.

When the pupil is dilated, one should consider mydriatics, myopia, excitement or emotion, irritation of the sympathetic nerves or paralysis of the third nerve. When the pupil is contracted, one thinks of myotics, irritation of third nerve or inhibition of the sympathetic. Normally, the pupil contracts to light, accommodation and convergence; however, disturbances in the motor portion of the reflex path of the third nerve may be exceptional. If such disturbance is in that portion of the reflex path which lies between the optic nerve (centripetal limb) and the third nerve (centrifugal limb), we find that the

Copyright, 1925, by A. R. Elliott Publishing Company.

reaction of convergence and accommodation is maintained, while the reaction to light is absent (Argyll Robertson pupil, so often associated with tabes and progressive paresis). This has also been found in certain tumors located in the region of the third ventricle. By pressure, these growths may produce similar findings. Attention is called to the cases that show contraction of the pupil to light, but are not aware of the presence of light. To these belong the types that have lesions high up in the optic pathway above the connected fibres between the optic and the third nerve.

We encounter patients who show normal reaction to light and accommodation, but a complete paralysis of convergence, with all extraocular muscles functioning normally. Regarding the frequency of paralysis of convergence as an early manifestation of disease of the nervous system, I would like to say a few words. The causes are many (3): tabes, multiple sclerosis, in three per cent. of the cases and probably as a result of other organic nervous diseases. Paralysis of the power of convergence, partial or complete, without disturbance in lateral movements (5), is a form of nuclear palsy which is often found in disseminated sclerosis. I have found this condition associated with syphilis, migraine, and intestinal toxemia. In the two last mentioned conditions, the paralysis is usually of transitory nature. As to the localization of the lesion giving rise to this condition, many theories have been advanced, but few facts have been given to substantiate them. It is thought by many that disturbances in the region of Deiter's nucleus in the medulla oblongata may give rise to the aforesaid symptom. Bernheimer believes that the anatomical site of the lesion is probably in the fibres connecting the nondecussating fasciculi of the two internal recti nuclei with each other, or connecting these fasciculi with the cortex. Edinger's views, as contained in the seventh edition of his lectures upon the *Structure of the Nervous System*, are that the centre of convergence may be formed by the large cell median nucleus of the ocular motor nerve, associated with the nerve cells for the rectus internus which lie on either side and near the median nucleus, and that these three groups together may form a centre for convergence; while Marina's investigations (6) have made it seem doubtful that such a centre in the oculomotor nucleus really exists. The majority of us, however, will admit the existence of such a centre, wherever it may be.

I have found six cases showing this condition: two acknowledged syphilis and had four plus Wassermanns, and two were suffering from gastrointestinal toxemia with negative Wassermanns. The fifth had a negative general and family history, and no cause for the condition could be determined. In the sixth patient there suddenly developed a dilated pupil on the left side, with loss of reaction to light and accommodation, and an accompanying convergence paralysis. The Wassermann reaction was doubtful.

The examination of the ocular muscles is of great importance in the early diagnosis of diseases of the central nervous system. It is well to notice the position of the eyes in the primary field, and have the patient perform the associated movement tests in the six cardinal positions. If diplopia is found, the tangent screen, with a red glass in front of one eye, readily enables one to locate the muscle or muscles involved, and in this way, phorias, trophias and paralytic deviations may be differentiated. One or more ocular muscles may be involved very early, and frequently diplopia is one of the first symptoms complained of, and may be a forerunner of a grave disease of the brain. This is especially true in lethargic encephalitis. In this condition, the prodromal symptoms are usually diplopia, perhaps associated with a headache or general bodily weakness. Upon examination, there is often found paresis or a true paralysis of one or more of the ocular muscles, and an associated sluggishness of accommodation.

I do not recall having ever seen a case of this disease, in which, at one time or another, the patient did not have symptoms of diplopia. In the ocular muscle palsies, the site of the lesion is, as a rule, in the nucleus of the supplying nerve or its trunk, and of all the muscles of the eye, the external recti are the most frequently involved, chiefly because of the long basilar course of the sixth nerve. Next in order come the muscles supplied by the third or oculomotor nerve, and lastly, the superior oblique muscle, which is innervated by the fourth nerve.

In cases of intracranial pressure, the external rectus is frequently involved, but this is of little value in localizing the site of the lesion. The cause of this early and frequent involvement is thought to be due to compression of the nerve trunk by a cerebellar artery (Cushing).

In lesions involving the nucleus of the third nerve, we may have, as a resulting condition, ophthalmoplegia externa, interna, or totalis. In the former case, the sphincter muscle and the muscle of accommodation are not involved. We often encounter isolated paralyses of the muscles supplied by the oculomotor nerve and which are not of nuclear origin. The reason for this may be explained by the fact that the fibres forming the third nerve are not closely united at the point of exit of the nerve from the cerebral peduncle. And it is because of this that paralysis of one or more of the muscles innervated by the third nerve may be encountered in basilar meningitis without paralysis of the whole muscular supply of this nerve. Paralysis of the superior oblique is rare but when found it usually is of basilar origin. However, it has been found in relation to tumors in the pineal gland (7).

When conjugate deviations are noted, we may readily assume that the lesion is central. The causes of this condition are many: apoplexy, epilepsy, certain tumors of the brain, and other conditions.

It is hardly necessary to discuss the value of testing the visual acuity, for we all realize the importance of having any refractive error corrected so that we may be sure the reduction of vision is not due to this. A routine examination of the fundus, and preferably under a mydriatic, often gives us the true picture of the changes with which we are confronted, and shows us what to expect. In many cases it enables us to make an accurate diagnosis, to give the neurologist information which helps him to localize the causative lesion, and enables us to form an opinion as to the necessity for surgical intervention and to furnish a fair prognosis as to the probability of blindness.

Perimetry is of untold value; therefore, a careful perimetric test should be made in every case and an accurate record of one's findings kept. By so doing, we can check up findings formerly made and so map out islands of blindness, and accurately determine the extent of involvement. We are able, by this method, also to make a differential diagnosis in many cases and frequently, before visible changes in the nerve head are perceived with the ophthalmoscope, are further able to make a fairly accurate localization of the lesion with the perimeter, and to differentiate the organic from the functional.

Before reporting several cases, I should like to discuss, briefly, the condition that is commonly termed migraine, or scintillating scotoma. This condition which may be defined as a neurosis characterized by paroxysmal attacks of headache, preceded by visual disturbances bizarre in character, is thought by many to be of hereditary origin and closely to resemble epilepsy, and to be caused by a disturbance in the circulation of the blood in the bloodvessels of the brain, probably an angioneurosis of the vessels in the calcarine cortex. However, I am not prepared to say whether the condition is hereditary or allied to epilepsy.

It has been my experience to find that these cases have, as a contributory cause, eyestrain produced by small refractive errors, frequently astigmatism against the rule, or one or the other cylinder off axis. In other cases, I have found a history of gastrointestinal toxemia with constipation.

In no way am I trying to discredit, or attempting to disprove any statements made by well known authorities who have gone much further and deeper into the question of the etiological factors underlying this condition; I am speaking only from personal observations.

Associated with visual disturbances, I have found one case that presented distinct paralysis of convergence which was transitory in character. The patient, on the subsiding of the attack, was found to have binocular single vision, thus showing that, whatever the etiological factor might have been, the visual centres were in some way affected, as well as the centre of convergence.

While taking the visual field of another patient during an attack, and making a fundus examination, I found he was not only apathetic, but that he frequently called objects by the wrong name (psychical migraine). This condition has been described in detail by Liveing (8) and Oppenheim (9). The only way in which I could account for these symptoms was by the extension of the angioneurosis to other areas of the brain. When taking the fields at different intervals, of two patients, the frequency of left homonymous hemianopsia was noted, and I thought I had made a discovery. A few days later, one of these patients had another attack and when taking the fields, I was surprised to find a right homonymous hemianopsia.

The onset of these attacks is described beautifully in many cases, beginning with zig zag lines and many colored lights, to a blurring of portions of objects. The latter is the most common type, the blurring gradually progressing to the point of blotting out definite areas of the fields and, at times, taking the form of homonymous hemianopsia, more intense on one side than the other. As the attack progresses, there is a contraction in the corresponding fields. Such an attack, as a rule, does not last longer than thirty or forty minutes and with the wearing off of the visual disturbance, the headache follows.

With the subsiding of these visual disturbances, I have seen the paralysis of convergence remain for forty-eight hours, and at the expiration of this time, the patient have orthophoria with perfect fusion of images.

Case I.—Migraine associated with astigmatism against the rule, convergence insufficiency and history of gastrointestinal toxemia. J. R., aged twenty-nine, white, male. Complaint—attacks of headache and blurred vision, associated with dancing lights in front of eyes. These attacks came on, as a rule, after the patient had been reading or studying. The family history was negative. Previous history showed the usual diseases of childhood. The venereal history was negative. The patient used tobacco moderately; had a good appetite, and slept well. Suffered from intestinal stasis and indigestion. Examination of eyes—vision 20/20 O.U., fundi and media normal and clear; examination of extraocular muscles showed twelve degrees of exophoria for near with a remote near point; retinoscopy showed O.D.+0.25 sph.+0.500 axis 180. With this correction, patient read 20/15; examination of visual fields, the first field, which was taken August 1, 1920, and about twenty minutes after the attack of blurred vision had started, showed left homonymous hemianopsia with a restriction in the corresponding halves in both fields. As the attack progressed, the entire fields of both eyes were contracted down to within thirty degree limits, after which there was found to be a sudden cessation of the blurring experience, and the fields cleared rapidly.

Two months later (October 5th), thirty minutes after the attack of blurred vision, the visual fields showed right homonymous hemianopsia, with restriction of the corresponding fields. The fields taken between the attacks were found to be normal, and no enlargement of blind spots noted. The patient's refractive error was corrected and he was advised to wear his glasses constantly. Convergence exercises were started and careful attention to the diet and gastrointestinal tract was advised, with the result that the attacks that previously occurred at frequent intervals have not occurred in a period of several months. Concluding, I will say that this, to my mind, was a case of migraine, due largely to a refractive error associated with an ocular muscle insufficiency, intensified by gastrointestinal disturbances.

Case II.—Paralysis of convergence, probably of syphilitic origin. E. H., aged forty-one, colored, male. Complaint—double vision. Past history of rheumatism. Venereal disease was denied. Present trouble started three years ago, following an attack of rheumatism. Patient began to see double at that time and condition has since grown worse. Examination reveals vision O.D. 20/100, O.S. 20/70 corrected to O.D. 20/20 with a+0.50 sph.+0.75 C ax vertical. O.S. 20/20 with a+0.70 sph.+0.50 sph. ax vertical. Fundi and media normal. Pupillary reactions normal to light and accommodation. Near point of accommodation 22½ cms. O.U. Extraocu-

lar muscle movements normal in all fields. Exotropia 14 degrees for near, 1½ degrees for distance. Tangent screen shows crossed diplopia in primary fields, not increasing in other fields. Patient unable to converge to the slightest degree. Neurological examination negative, except some inequality of knee jerks. X ray of skull and paranasal sinuses negative. Blood Wassermann positive. This was a case of convergence paralysis and, in my opinion, due to syphilis. Patient was put on mixed treatment and intravenous injections of salvarsan. His condition improved.

Case III.—H. J., aged twenty-two, colored, male. Complaint—double vision. Family history negative. Present history negative. Venereal history denied. Present trouble dated back seven years, when patient suddenly noticed that objects appeared double. Condition had progressed slowly. Examination revealed vision 20/20 O.U. Fundi and media clear. Pupils reacted to light and accommodation. Near point of accommodation 12 cms. O.U. Near point of convergence 225 cms. Extraocular muscles examination showed 7½ degrees of exotropia for near. Orthophoria for distance. Associated movements were test normal in all positions. No individual muscle paralysis. Tangent screen showed crossed diplopia in primary field, remaining the same in all other fields. Neurological report negative. X ray of skull failed to reveal any pathological findings. Paranasal sinuses negative. Blood Wassermann positive. Patient was on intravenous salvarsan and mixed treatment, and his condition had, to date, remained stationary, with no improvement of ocular symptoms.

Case IV.—S. A., colored, female, aged forty-six. There suddenly developed dilated pupil on the left side, with inability to fuse objects. Past history of no consequence. Venereal history denied. Examination of fundi and media clear and normal. Right pupil reacted to light and accommodation, and normal in size. Left eye showed complete internal ophthalmoplegia, with a fixed pupil that did not react to light and accommodation. Consensual reflex from right to left absent, from left to right present. Examination of extraocular muscles showed no individual muscle paralysis. Crossed diplopia in primary field and not increased in any other field. Near point of convergence 150 cms. Blood Wassermann questionable.

This, I think, should be looked upon as convergence paralysis associated with an ophthalmoplegia interna, and tends to substantiate the teachings of Edinger in locating the centre of convergence in close proximity to the nucleus of the oculomotor nerve. As to the doubtful Wassermann, I am skeptical. However, the left pupil returned to normal size in less than two weeks under intensive treatment with mercury and iodides.

A routine examination, similar or as outlined, should be adhered to in the examination of every patient. By so doing, an insight may be gained, in many cases, as to the condition of the central nervous system.

Every patient complaining of headache, especially of migrainous type, should be refracted and the diet regulated and watched, as this condition is frequently due to an astigmatic error or some disturbance in the gastrointestinal tract. In the examination of the ocular muscles, it is well to bear in mind the importance of convergence paralysis, as it is a symptom more common than is generally believed, and frequently of syphilitic origin.

The Diagnosis of Acute Conditions of the Brain

With Special Study of the Spinal Fluid and Reference to the Child

J. VICTOR HABERMAN, M.D.,
New York

In the case of socalled brain symptoms suddenly appearing in a person up to then well, or at the moment suffering from some other condition, one will think of encephalitis or meningitis, or, if trauma has been encountered, of fracture of the skull, concussion, contusion, edema, hemorrhage, encephalitis, meningitis, or combinations of these, pachymeningitis (after trauma, chronic alcoholism, or in hemorrhagic diatheses), or, again, shock, psychosis or psychoneurosis. Brain symptoms of systemic conditions—nephritis, eclampsia, diabetes, etc.—must also be thought of, apoplexy (from arterial disease and hemorrhagic tendencies) (I), embolism (from a rheumatic heart, or, in the course of diphtheria, scarlet, typhoid, pneumonia, erythema nodosum or septic process) and thrombosis (luetic, typhoid, carbon dioxide poisoning), while one will have to make special survey from the angle of otitis, parasites getting into the head, and, finally, endogenous and exogenous toxins, drug and chemical poisoning.

Where long bones have been fractured or broken, a fat embolus may give cerebral symptoms. Such embolism seems to be rare after operation, yet it might be thought of. Thus, I saw a central facial, after an appendectomy, which could possibly be interpreted in this way (and there seemed no other interpretation).

In some cases, the lumbar puncture achieves the

diagnosis, the liquor findings being characteristic, or even pathognomonic; in others, it clinches an opinion clinically attained, while in still others, it serves but negatively, or even, at times, confuses the issues. It is necessary, therefore, to bear the diagnostic possibilities in mind, and collate the clinical data with the liquor findings and laboratory norms.

Among the encephalitides, we have a primary group: Heine-Medin, influenzal, epidemic (Economo), and a type which might be labeled "without evident or known etiology," this last being of two forms: a, with definite hemorrhagic encephalitis lesions, and, b, without discoverable lesion, i. e., without anatomical basis,—and a secondary group: consequent to the infectious diseases, to the exanthemata, to toxemia, autotoxemia and intoxications (food, ptomaine, various drug poisons), and to trauma. (For details, cf. 1.) The possibility of a syphilotoxic encephalitis on the basis of lues has also been brought up (Oppenheim). The unusual primary forms of sunstroke and heat stroke (1), and an unusual secondary, due to dysentery (2), may be mentioned.

Among the meningitides, we again have several primary forms: epidemic, tuberculous (II), possibly influenzal (though this is unusual), and possibly a primary serous form (very unusual), and, rarely, a serous meningitis as an expression of Heine-Medin disease—and the secondary: tuberculous, pneumococcal, staphylococcal and streptococcal, influenzal, diphtheritic (III), gonococcal, syphilitic, enteritic, etc., and the "sympathetic" (aseptic purulent) and serous (IV) forms.

One will also think of a pachymeningitis hemorrhagica interna, or a hematoma of the dura, after trauma, and especially after trauma in a chronic alcoholic or an arteriosclerotic, the first coming at times spontaneously in the alcoholic or where a hemorrhagic tendency exists.

Syphilis usually causes a chronic condition, i. e., a meningoencephalitis, yet it can (rarely) produce an acute febrile meningitis (Pette's study (7), out of Nonne's clinic). Oppenheim also thought that a nongummatous simple meningitis could occur. Besides, we must reckon with acute exacerbations and flareups, and possibly even with an acute gummatous form. Of this subject of syphilis, however, more will be said below.

Acute brain symptoms similar to apoplexy (or sometimes to epilepsy) are also encountered in paresis, multiple sclerosis, brain swelling and socalled "sudden tumor." (For differential details in these latter forms, cf. 8.)

The normal spinal fluid (9) is clear, has a specific gravity of 1005-1010, a pressure of about 90 to 120 or 130 mm. of water, contains only a few cells (lymphocytes) to the cmm., three or four, at most, five or six. It contains but minute quantities of albumin —0.02 or 0.03 to 0.05 per cent—and globulin. The sugar content is about 0.06 to 0.09 per cent (10). The Wassermann, whether with 0.02 or 1.10 c. c. of fluid, is, normally, negative. Where the fluid is turbid, this is due to the presence of white cells (pleocytosis)—[pus]—and signifies irritation or inflammation of the meninges. Where bloody, the color may be due to injury to subdural veins in making the spinal puncture. This bleeding, however, rapidly stops, and the following portions of the fluid are clear. Where the blood is due to abnormal spinal fluid (bleeding from brain, cord or meninges), it continues to flow out red (sometimes yellowish), and, after standing, does not coagulate (as does the former). A moderate pleocytosis occurs after lumbar puncture, also on the injection of serum or drugs into the dural sac, and through (neighborhood) irritation of suppurative process in the ear or mastoid. In diabetic coma, the spinal fluid contains acetone.

As a routine procedure, I would suggest the following: Note the blood pressure. High readings will at once suggest systemic conditions (nephropathies, eclampsia, uremia, etc.) (the uranalysis may give corroborative data (5), or may point to heightened intracranial pressure. Take blood for a Wassermann (it is wise to make this in every case—even when syphilis doesn't seem possible), differential white cell count (a high leucocytosis suggesting suppuration somewhere in the body, or, in cases of head injury, a moderate leucocytosis pointing to fracture of the skull (12)) and smears (bacteria). In some cases (tuberculosis or suspected tuberculosis), the corpuscle sinking time (sedimentation test) may add valuable data (VI):

Blood pressure
Uranalysis
White cell count
B.W., i.e., Blood Wassermann
Sedimentation test
(Mátéfy)

Then proceed with the liquor examination proper, i. e.:

Spinal fluid pressure (VII)
Appearance (macroscopic)
Cell count
Presence of bacteria
Phase I (Nonne-Apelt)
Albumin content
Sugar (glucose: Fehling's reduction)
L.W., i.e., Liquor Wassermann
Meinicke (3rd modification)
Pandy
Mastix and colloidal gold reactions

The particular tests will be discussed as they come up under the various conditions and diseases here studied. Several facts, however, may advantageously be brought out before proceeding.

Albumin as such is found in the spinal fluid in all inflammatory conditions of the meninges, but also in syphilis (including tabes and paresis), tumors of brain and spine. One will find it in chronic meningeal (or cortical?) irritation, kept active by cysts and softenings, manifesting itself through epileptic seizures (14).

The *globulin* content in the spinal fluid is practically nil in normal individuals. A positive globulin test (Nonne's Phase I, or Pandy) means organic disease of the central nervous system, but not necessarily syphilis. It never is found in an individual with an organically sound brain and spine, nor in cases of functional nervous disease (15). Nonne comments that no Phase I is ever found in the neurasthenic, hysterical or epileptic who once was syphilitic (but who has no syphilis now). It thus decides between the neurasthenia of early paresis and the neurasthenia of an individual who once was syphilitic—but now only has neurasthenia. In other words, it is present in both syphilitic and "metasyphilitic" disease (VIII). It cannot differentiate between syphilitic and nonsyphilitic organic disease of the nervous system. According to Beltz (17),

it is present in inflammatory conditions of the meninges, both tuberculous and suppurative, and also (but weak) in meningeal irritation in pneumonia and acute leucemia, and after an epileptic attack. These facts, of course, do not apply to albumin as such which may be found in both organic and many functional nervous diseases. There are times when the globulin test shows up in syphilis (sometimes with pleocytosis, sometimes without) even before the Wassermann (18). It is sometimes absent, however, in lues cerebri, especially the arterial form.

A blood Wassermann means that the patient once had, or still has, syphilis (i. e., has some spirochetes somewhere in him, or spirochete products—Nonne), but not that the presenting disease is necessarily syphilitic. (Occasionally it is met with in recent scarlet, malaria, leprosy, recurrens and possibly multiple sclerosis. Occasionally it is absent, in spite of obtaining cerebral syphilis. In tabes, it is absent in thirty to forty per cent of cases—though they are syphilitic.)

The spinal fluid findings may refer to the said lues, and need not be evidence of the presenting disease. Absent *liquor Wassermann* by no means precludes syphilis. The reaction is often negative in cerebrospinal syphilis, rarely also in paresis. According to Nonne, an isolated weak liquor Wassermann need not even be positive for nerve lues. If a nervous disease is present, and the liquor Wassermann is positive, then the disease is probably syphilitic.

HEINE-MEDIN DISEASE.

Of the encephalitides, let us first review the Heine-Medin form:

Heine-Medin disease usually besets a previously entirely healthy child, occasionally with prodromata, more often without. (In the great Swedish epidemic, they were rare, though Brorström (19) mentions stiffness and spasms occasionally preceding the paralyses). One has spoken of this prodromata stage as the *preparalytic stage*. There is, however, nothing whatsoever characteristic about this infection. The onset may be sudden, peracute or gradual and protracted. A number show a "forestage—remission—recidive" progression. This has sometimes been termed the dromedary type of case. It may run its entire course in two or three days, or a week, or over a longer period. The temperature may be high, low or absent.

The onset is like that of any infectious disease: temperature, headache, vomiting, frequently loose bowels. Very rarely there is a convulsion. Often, pain is present "all over," or especially in the head, neck, back and stomach. Eruptions of various types may be seen—or may be absent. If in the midst of an epidemic, and this is all there is of the sickness, one will say abortive poliomyelitis. If not in an epidemic, one will say grippe or gastrointestinal attack, or, sometimes, sore throat. Or, again, rarely, a grave condition may ensue, with convulsions or coma—the picture being undifferentiable from tuberculous or epidemic meningitis. In some abortive cases, merely the patellar reflex may be absent, or there is a passing meningeal phase.

Then comes the *paralytic stage:* after a day or two, or three, something is added to the above—paralyses. This gives the diagnosis (though spinal puncture may already have intimated it). The paralyses come rapidly, and are in full effect from the start (differing thus from polyneuritis). In most cases, the paralyses are flaccid, and in the extremities, with loss of tendon reflexes; in many cases, they involve the cranial nerves; in a rare few, they are spastic, and indicate cerebral mischief.

There is intense sweating, great hyperesthesia and nuchal pain on extending the head. There may be stiffness and pain in the back. Trembling and twitching may be noticed, drowsiness, retention of urine.

Blood and lumbar punctate show the following—and the findings here hold good for conditions in which cortical (encephalitic) involvement is not present, but merely disease of the brain stem, or, indeed, of the spinal form itself, as all forms show a meningitic irritation (reaction):

A blood leucocytosis polymorphonucleosis (20).
Pressure of liquor usually increased.
Usually clear (there may be a slight opalescence).
Cells increased (pleocytosis: preponderantly mononuclears) (15 to 20-1000 or over; 450 average [but lower averages have also been given, i.e., 20 to 100]).
No bacteria are found.
Albumin is increased.
Globulin increased (slight, moderate, more often, marked).
Glucose (Fehling's always well reduced [but Fehling's is reduced by most other spinal fluids, too]).
(A web or fibrous net is occasionally seen after standing.)
Colloidal gold curve corresponds to that of a weak syphilitic spinal fluid (IX).

These are the usual typical findings. But many findings are atypical: thus, one will come upon cases in which the polymorphonuclear cells are increased, some showing over fifty per cent. of these cells (23). In only thirty-nine out of fifteen hundred fluids of the New York Health Department did polymorphonuclears predominate. Such fluids are turbid, and then must be differentiated from other turbid spinal fluids, namely, early purulent meningitis (in which case the cells show ninety per cent or more polymorphonuclears, and the specific bacteria are found) and tuberculous meningitis. (There are, however, some cases of epidemic and tuberculous meningitis in which the respective organisms are not discovered). Where the fluid is clear, one will have to differentiate Heine-Medin disease from tuberculous meningitis (X) (the clinical course is most dissimilar, l. c.), unusual early cases of purulent meningitis, syphilis of the central nervous system (XI) (especially acute syphilitic meningitis) and serous meningitis.

This last may cause difficulty, because there is a form of Heine-Medin disease spoken of as the meningeal (or meningitic) form. During the last epidemic, Netter, of Paris, called attention to the fact that this form was especially prevalent in France. He found the clinical picture very similar to that of cerebrospinal meningitis. Both these diseases seem to occur epidemically at the same time. Here, a serous meningitis obtains, with high pressure, pleocytosis, positive Nonne-Apelt, possibly a web in the liquor. Clinically, one finds retraction and stiffness of the neck and nuchal pain, occasionally slight opisthotonus. The diagnosis of meningitis may be made—until typical Heine-Medin paralyses appear. But Wickman (24) also pointed out that Heine-Medin disease may occur as a meningitis serosa, without the appearance of any paralyses. Such cases he believed could

no doubt be found among those misdiagnosed as meningismé. Sporadic cases seem rare, yet do occur, as the following case shows, and must be diagnosed by exclusion:

Case I—I recently saw a case with Dr. R. A child of ten, presumably healthy, became restless during the night, screaming out several times; complained of headache. On the following day, there was pain in the legs, and a temperature of 102°. There had been no vomiting or chill, and no drowsiness. The child, in fact, was remarkably alert throughout his entire illness. The following day, on examining the child, I found difficulty in flexing the head, an attempt causing considerable nuchal pain, and slight stiffness in this region. Kernig on the left leg; weakness on the right. After three days, the child was entirely well.

Two rare types of fluid have been described (J. B. Neal, report of New York Department of Health, l. c.), one a hemorrhagic form, the blood cells being diffused throughout the spinal fluid. These are cases in which the hemorrhagic process has been unusually severe. The second is a yellowish fluid (syndrome of Froin), where the hemorrhage has occurred several days previously.

The spinal fluid may also be blood tinged, through injury of a vessel in the canal, in making the puncture.

EPIDEMIC ENCEPHALITIS.

Epidemic (lethargic) encephalitis may begin suddenly, usually without prodromata. In a variously estimated, yet very considerable, percentage of cases, influenza has preceded a week to several weeks or more (occasionally a year (XII)). Or a fevery stage may precede, with grippal symptoms, after which, the disease proper, evidencing eye signs and somnolence, sets in. The onset may be with general malaise, fatigue or weakness, dizziness, possibly pains here and there—occasionally severe—(joints, back, nape, mastoid region), moderate headache (rarely intense, as in meningitis) and some nausea and vomiting—which usually does not last long. Temperature may or may not be present, and, save in bad cases, is never high (XIII). An initial chill does not seem to occur, or but unusually. Mild meningeal symptoms (more properly speaking, intimations of such), on the other hand, are often noted: sensitiveness of the bulbi to pressure, a very slight tendency to nuchal rigidity and nuchal tenderness. Rarely Kernig's sign is present. Some observers noticed this meningeal reaction more than others, some but rarely (Nonne (28)); Economo, on the other hand, terming it meningismus, believed it typical and common. Thus, the following may be taken as a somewhat characteristic onset:

Case II—Patient N. N., early in December, is said to have had grippe. In bed several days with cough, malaise, headache, "all in." After a few days, recovered. Four weeks ago, patient, on rising, felt things swim about her, and had some ear ringing. Soon she noticed she saw double, felt fatigued, with overwhelming desire to sleep. She slept all day and all night, had to be awakened to eat. She fell asleep while eating. Then she noticed she did not see well, things appeared dim and unclear (accommodation disturbance). Severe constipation obtained. When she attempted to walk, she swayed.

Economo's first case or two may also here be cited (they will have historic interest):

Case III.—M. H., thirty-one years old. Taken sick suddenly with chilly feeling, headache and clouded sensorium. Since then, is "lost," apathetic, takes no food. In the eight days prior to hospitalization, had a staggering gait. Brought in three weeks after onset, supported by two persons. Sensorium lightly clouded, mild bilateral ptosis and bilateral external oculomotor paralysis. Pupils react. On the right side, exaggeration of reflexes in lower extremity.—Patient sleeps all day; frequent yawning. Reacts to very loud questioning slowly and sparely, etc.

Case IV—R. H., seventeen years old. Acute onset February 3rd with temperature 39.5°, confusion, headache in occiput and nape. Stiffness of the arms and legs. Patient was somnolent from the start, held her eyes closed, but talked incessantly "irrational stuff." February 5th in hospital. Temperature, 39.2°. No spontaneous movements, lies on back, asleep. Light rigidity of extremities, but no abnormal reflexes. Sensorium clouded, yet is arousable on questioning, and answers rationally—is oriented. Keeps eyes closed. Pupils react. Possibly left abducens paresis, etc.

Unique is the fact pointed out by Strümpell (29) that the patient can nearly always tell the very day, often the very hour, his illness began. This acute definiteness of onset, however, though the rule, may at times prove but subacute, or even a gradual affair, yet, again, on the other hand, be quite fulminant. The disease has, in fact, come on so apoplectiform like as to necessitate differentiation from real apoplexy (XIV).

The spinal fluid in epidemic encephalitis (31) is in no wise characteristic. It may be normal, as in Nonne's [l. c. (28)] and Umber's (32) series, or somewhat abnormal. One might sum up as follows:

Normal or slightly increased pressure, occasionally high.

Occasionally very high. Some of these cases also showed optic disc changes, and gave a picture very similar to brain tumor (cf. case of Winter's (37).

Clear occasionally: rarely blood tinged or yellow greenish tinge.

The cell count shows a mild pleocytosis. This may, at times, be very low (rarely 6 to 9 to the cmm.), occasionally 100 and over (in a few cases, 400 to 500). (Economo found 10 to 20; Plaut, 40 to 60; Barker, 10 to 100; Bonhoeffer, and also Forster (38), a "strong lymphocytosis" in all.) Polynuclear cells are present, and proportionately high in some series (XV) (Economo's).

No organisms found.

Nonne-Apelt negative or weak positive.

The complete albumin is increased (with Nissl test, between 0.5 and 5.5%, according to Economo).

Slight coagulate (fibre) in occasional cases.

Globulin sometimes normal, sometimes excessive (greatly increased in some series—Barker, Neal).

Fehling reduction, normal or increased (XVI).

Colloidal gold test not characteristic.

INFLUENZA.

As there may be confusion at times as to whether one is dealing with influenza proper or epidemic encephalitis, it might be well to point out that in influenza, even where severe, and with cerebral manifestations, namely, with outspoken psychotic disturbances, the spinal fluid shows nothing abnormal (45). A hemorrhagic encephalitis may, however, occur (cf. 1 for differential study on influenzal encephalitis vs. epidemic encephalitis).

From the clinical angle, Leichtenstern (46) came to somewhat the same conclusions. He pointed out that the onset of influenza is almost without exception a sudden one—hence the name lightning catarrh given to it in 1782. At the very beginning—i. e., without prodromata—or when at its height, under soaring temperature, apoplectiform, hemi- or monoplegic paralyses may appear, with accompaniments of delirium, coma, etc. Elsewhere Leichtenstern notes that the disease may begin with a sudden vertiginous siege or obfuscation of the senses, or an "apoplectic" or epileptic attack, accompanied by unconsciousness of several hours' duration. (The quotation marks about apoplectic are his own). Such a case not infrequently clears up after a few days. In children, even if but seldom it happens that a deep faint or convulsion, or a convulsive seizure, with subsequent long continued unconsciousness, may initiate the attack. Or, again, a sudden terrible vertigo may come, followed by sopor or unconsciousness. Such an attack may also be followed by mild influenza symptoms, and rapidly clear up. In one case, there was no temperature with the apoplexy but the next day, high fever and grippal symptoms. After three days, the patient was quite well again. He also mentions the important fact that the picture at first may be that of an acute psychosis (initial delirium or stupor, fear, delusions, confusion, mania), and, in fact, without any temperature at the time. These cases are often diagnosed as acute psychoses—only in a few days suddenly to clear up. He attributes these severe initial attacks to acute poisoning through the influenzal toxine acting through the circulation with unusual intensity, and primarily on the brain—not to encephalitis. An influenzal encephalitis, however, occurs, with a tendency to minute (flea bite) and larger hemorrhages, with paralysis of an entire side, or limb, or an isolated cranial nerve (XVII), or aphasia. All these symptoms may clear up within a day or two.

An influenzal meningitis also occurs, though not frequently. Nor is the condition dealt with (bacteriologically) entirely clear. In the 1918 epidemic, various etiological organisms were found (pneumococcus, streptococcus, etc.), but not the Pfeiffer (47, 48). However, a Pfeiffer meningitis does occur, giving a purulent spinal fluid containing the Pfeiffer organism. The cases are not common (XVIII).

T. M. Rivers (50) suggested the indol test on the spinal fluid for rapid diagnosis of bacillus meningeal infections. He found this of diagnostic value.

Retinal bleeding (51) and flea bite petechiæ in the tympanic membrane will point to influenza.

(To be continued.)

The Correct Conception of Thoracic Empyema and Its Rational Physiological Treatment

A. L. SORESI, M.D.
New York

The method of treatment to be presented in this paper was originated the latter part of the war (1918-1919) during the epidemic of influenza and has been used since by several surgeons and by myself. More than one hundred and fifty cases have been treated by this method, the age of the patients ranging from six months to fifty-eight years. While not presenting statistics, which would have to be incomplete and therefore valueless, we may state that in the thirty or more cases treated in this country by Honan, Kellogg, Lewson, Lutton, at the Flower Hospital, by Scannell and Smith at the Greenpoint Hospital, and by me at the same institutions and at the Sea View Hospital, the average hospitalization time was sixteen days with no mortality.

The method is based on these physiologically, mechanically, clinically and psychologically rational principles: it takes into consideration the defensive rôle of the pus; it preserves the negative pressure of the chest, compelling the retracted lung to expand gradually, continuously, while the pus is automatically drained out as fast as it forms. It does not require rib resection. It allows a maximum comfort to the patient, being painless and not requiring any painful or even annoying manipulation, such as change of dressing, irrigations, aspirations and allowing the patient out of bed immediately or a few days after the operation. Clinical experience has shown that the method is exceedingly simple in its application once its basic principles are understood. Any general practitioner possessing enough surgical sense, training and skill to do good minor surgery can apply the method under all circumstances. The method is most economical because it shortens the time of treatment, does not require expensive dressings, apparatus or special expensive attendants. It prevents, practically in all cases, the complications so commonly observed in cases of empyema too numerous and well known to be even mentioned.

RATIONAL CONCEPTION OF THORACIC EMPYEMA

A clear and rational understanding of what empyema thoracis represents is indispensable to its rational treatment. The following few considerations, although elementary, seem necessary in order to make the problem clear. Negative pressure in the thorax allows the easy and alternate expansion and contraction of the lungs. The pleura lines two completely closed cavities surrounded by bony and muscular structures, practically unyielding, and contains two expansive, elastic and easily collapsible organs—the lungs, separated by the mediastinum. The pleura in normal physiological conditions allows the lungs a free expansion without friction, and contains for this purpose a small amount of fluid. The amount and function of this fluid can be compared to the amount and function of the lubricant found between the cylinders and the pistons in motors and

its amount is regulated by a well balanced production and absorption.

In certain pathological conditions the amount of the fluid found between the visceral and parietal pleurae increases. Some organs must obviously be dislodged by the fluid which, according to physical laws, cannot be compressed and which accumulates in the pleural cavity. Evidently, the lung corresponding to the pleural cavity in which the fluid accumulates will therefore be first dislodged and compressed.

What follows the compression of the lung? A lung that is compressed will not expand and contract, therefore, the parietal and visceral pleuræ will not slide over each other, or their movements will be limited more or less: this means that the pleura is put completely or partially at rest. The great importance of such rest is easily understood. The organs contained in the thoracic cavity are normally subjected to continuous, rather strenuous movements. The diffusion of inflammatory and infective processes is favored by active movements of the affected organs. Whenever inflammation or infection of any organ occurs, nature tends, first, to spare the affected organs; second, to limit any infective or inflammatory process from spreading; third, to start immediately a process of reconstructive defense of the affected organs. In order to obtain these important aims nature, as a first step, tends to put at rest the infected or simply inflamed organs. In inflammation of the pleura, nature tries to put at rest the infected or inflamed pleura. The only manner in which nature can put the pleura at rest is to limit or prevent completely the sliding of the visceral and parietal pleuræ over each other; this can be accomplished only by fluid accumulating in the pleural cavity, which, by preventing movements of the pleura, puts the pleura at rest. We can therefore logically assert, as an incontrovertible fact, that the accumulation of fluid in the pleural cavity puts the parietal and visceral pleuræ at rest; that, according to physiopathological laws the infected or even simply inflamed pleura needs such a rest; that consequently the presence of the abnormal amount of fluid in the pleural cavity represents the most valuable natural process of defense; that unless we can substitute a more valuable medical process of defense than the accumulation of fluid, devised and put in action by nature, we have to act in such a manner that the work of nature is not hampered.

The defensive character of the presence of an abnormal quantity of fluid in the pleural cavity that puts at rest the affected lung and pleura is confirmed by the following daily observations: First, the death rate of patients, whose pleural fluid is evacuated early, is much greater than when evacuation is delayed. Second, during the acute or subacute stages, fluid in the pleural cavity forms again and accumulates a few hours after it has been removed.

We have dealt with the subject of an abnormal quantity of fluid in the pleural cavity without taking into consideration the different characteristics of this fluid, which may be clear, sterile, thick or purulent, and the clinical evolution of the accumulation of this fluid. We wanted first to establish the fact that this abnormal fluid represented always, in every case, a most valuable process of defense, before discussing the best means of treating rationally the complications that may arise on account of the presence of such abnormal fluid.

We have, however, to meet the objections that can be raised against this defensive conception of the presence of an abnormal quantity of fluid in the pleural cavity, when this fluid might appear to be directly or indirectly the cause of serious symptoms, complications and even death. Clinically we can divide the cases in which accumulation of fluid occurs in the pleural cavity into extremely acute, acute, and subacute cases. In the extremely acute cases the patients generally die in a few days, but not on account of a rapidly accumulating abnormal quantity of fluid in the pleural cavity which obviously could easily be decreased by aspiration, but notwithstanding such rapid accumulation (which *per se* might cause dyspnea, cyanosis and other conditions), that is, notwithstanding the quick and prompt attempt on the part of nature to prevent the rapid spreading of dangerous and destructive pathological processes. To charge the death of the patient to the abnormal accumulation of fluid in the pleural cavity would be as logical as to charge the destruction of a building that was the prey of a sudden and powerful fire to the water that was used in order to extinguish it, no matter what damage the water under great pressure and in great quantity might have caused *per se*. In all cases, whether extremely acute, acute, or subacute, the abnormal accumulation of fluid in the pleural cavity alters the physiological relations and functions of the organs, and therefore does cause damage and trouble, at times serious.

Firemen, extinguishing a fire, always cause damage and trouble, but no one would doubt their value in preventing the spread of the fire and no one would hamper their work, because of the possible and inevitable damage and trouble that positively follow. The same considerations should lead the physicians in dealing with accumulation of fluid in the pleural cavity. No matter what damage the accumulation of fluid has caused, this accumulation is always the best means of defense that nature can muster. It is our duty, as intelligent physicians, to help, not to hamper, the good work of nature when complications arise, or prevent such complications whenever it is possible.

PATHOGENESIS

Discussion of pathogenesis, varieties of empyema, diagnosis, prognosis, treatment of the *causa prima* is omitted here for brevity's sake. We wish, however, to emphasize that the x rays are invaluable for proper diagnosis and prognosis. The causative agents must be sought first, because no empyema can be cured until and unless the causative agent has ceased its activities and therefore it is imperative to know this causative agent or agents. So it will be easily understood that empyema, caused for instance by the presence of an infected foreign body in the pleural cavity, or by a pneumococcus pneumonia, or by a subphrenic abscess, or complicated by tuberculosis, have different etiological factors that must be dealt with *secundum artem,* before the actual rational treatment of empyema is begun. In no case of empyema could a cure be expected as long as the foreign

monic process is still active, or until the subphrenic abscess or the complicating tuberculosis are properly treated.

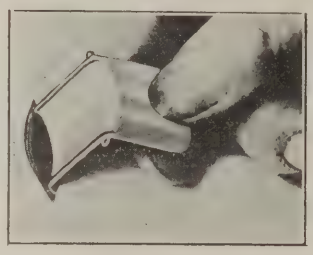

FIG. 4.—Manner of applying the cannula. The lower half is introduced first by holding the long flange, while the short flange turns around the rib and enters the pleural cavity.

BASIC PRINCIPLES OF RATIONAL TREATMENT OF THORACIC EMPYEMA

The general management of cases of empyema can be thus outlined. The patient is kept at rest; general condition studied carefully and dealt with accordingly, with a view to bringing improvement where improvement is indicated. The condition of the lungs, mediastinum, diaphragm, heart, kidney, and other organs, and such complications as constipation, anemia, poor digestion, neurotic conditions, tuberculosis, demand the special attention of the attending physician who must meet the peculiar needs of each patient according to age, sex, temperament, surroundings and other conditions. Food plays an important part in helping this class of patients. Abundant protein diet, pleasing to patient's taste, supplemented with sugar and vegetables, will help a great majority of patients, who, generally speaking, must be overfed, when it is possible. Arsenic, judiciously employed, is also very helpful. One of the most important factors helping patients suffering from empyema is comfort, especially after the operation. Repeated dressings which are more or less painful and cause great discomfort and frequent examinations do not allow the necessary physical and psychic rest, which is more essential the more septic and depressed the patient.

The direct treatment of accumulations of abnormal fluid in the pleural cavity must be based on the fundamental principle that the presence of this fluid represents a process of reconstructive defense.

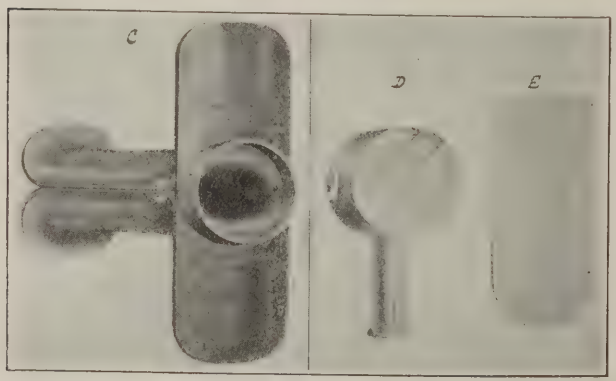

FIG. 3B.—Author's cannulas. C, showing the two valves of Fig. 3A fitted into each other, forming a large oval channel. D, cap to be applied to ring in lower half of cannula. E, rubber valve that fits in space left between cap and ring, and completely closes the oval channel formed by cannula.

Removal of pleural effusion.—Abnormal fluid, whether clear and sterile or purulent, should not be evacuated if the cause which compelled the pleura to produce it is not also removed, or its activity has ceased. The early expansion of the lung would only tend to the renewal of the activities of the pathological process and useless wearing out of the affected organs.

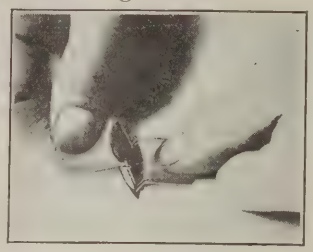

FIG. 5.—The upper half is applied by introducing its ridges in the grooves of the lower half and making the short flange turn around the rib.

Exceptions.—Removal of small quantities for diagnostic purposes, of larger quantities in order to relieve excessive pressure as often as the patient's comfort requires, until the process that caused the accumulation of fluid has subsided, or is removed *secundum artem.* The amount removed each time should not help the expansion of the lung of the affected side, but only relieve pressure on the mediastinum and the other lung and make the patient comfortable. An exception may be made in the rare cases where the pleural fluid is so highly toxic as to imperil the patient's life.

FIG. 6.—The two halves are put together by introducing the points of the upper half in the eyelets of the lower.

The line of treatment must take into consideration mortality immediate and late: the more or less rapid and more or less complete or ideal recovery. Immediate and late mortality is favored by general poor management of the case, too early operation, general anesthesia, improper operative technic; late mortality is favored by complications due to improper operative technic and poor aftertreatment. Therefore we must

First.—Study each case carefully. Do not take for granted that the case is a simple one. The most difficult and complicated case might at first appear to be a very easy and simple one.

Second.—Delay operation, as outlined above.

Third.—Use local anesthesia in all cases. General anesthesia in empyema is a surgical crime.

Fourth.—Avoid injuring the diaphragm, entering the peritoneal cavity, wounding of intercostal blood vessels. Do not break adhesions. Doing so opens new avenues to infection, causes hemorrhage, favors tearing of lung and pleura, formation of more adhesions: expansion of lung is not helped. Avoid collapse of patient by preventing rapid inrush of air in pleural cavity and sudden evacuation of great amount of pus. Do not resect ribs unless indispensable: rib resection favors osteomyelitis and formation of chronic sinuses.

Basic physical principle for the cure of empyema.—No matter what are the pathogenesis, the general condition, age, temperament or sex of the patient, or the complications, one physical condition, the im-

portance of which is too often overlooked, must be fulfilled before the patient is cured. The pleural space occupied by the fluid, whether clear or purulent, must be filled again by the lung or obliterated in some manner. On this point we shall base the criticism of the different methods of treating thoracic empyema in the fifth part of this paper.

Here we shall only remind that the normal lung expands because negative pressure in the pleural cavity compels it to expand. When we open the pleural cavity negative pressure has ceased to act and the lung fails to expand, and, as the lung is surrounded by a rigid bony cage, a hollow space results. The time treatment must be continued will be exactly that required to fill such hollow space, either by the lung itself, helped by the soft structures surrounding it, or by a surgical collapse of the bony cage.

It is selfevident that any method of treatment that does not reestablish the negative pressure of the pleural cavity will fail to obtain a rapid cure. Evacuation of the pus contained in the pleural cavity, while the negative pressure is preserved, is the fundamental basic principle of our direct method of treating empyema.

Broadly speaking, the conditions which the surgeon has to meet are 1, the presence of pus in the pleural cavity; 2, the retraction of the lung; 3, the poor general condition of the patient, who might suffer from complications, other diseases, or both; 4, the thickening and infection of the pleura; 5, occasional adhesions. Any form of direct treatment must therefore aim to 1, evacuate the pus present in the pleural cavity at the time of the operation and allow complete drainage of the pus that will form later. The means used for drainage must not, however, be the direct cause of pus production. 2. Favor early gradual expansion of the lung; simultaneous drainage of pus and expansion of lung. 3. Take into consideration and meet the peculiar conditions and needs of each individual patient. 4. Help the natural forces in bringing the pleura back to normal physiological conditions. 5. Dispose of the occasional adhesions. It is essential that these five factors work harmoniously—teamlike—and, at the same time, each help the other. If these factors do not work harmoniously they will work antagonistically, each handicapping the other, as would a team of horses, each horse pulling in an opposite direction or not at the same time. We feel that by basing our assertion, not only on our results, but on the results obtained also by different surgeons, we may conserva-

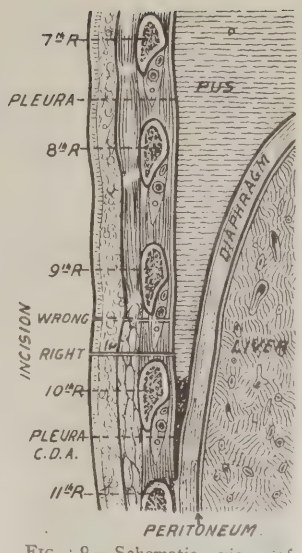

Fig. 9.—Schematic view of correct incision.

tively state that the method to be described actually meets successfully the five conditions mentioned above.

AUTHOR'S METHOD

Before operation aspirate some pus when a large amount is present. To be precise: supposing the operation is scheduled for 11 a. m., pus should be aspirated at 8:30 a.m. and again at 10 a.m. These aspirations will lessen the danger of collapse at the time of operation and should be made in the intercostal space in which the operative incision is going to be made later. The intercostal space selected generally is located between the eighth and ninth ribs or ninth and tenth, the incision being made along the scapular line.

FIG. 13.—Shows schematically how patient may walk about carrying bottle for collection of pus.

Position of patient—When possible the patient should be operated in the sitting position, otherwise the position shown in Fig. 1 is satisfactory. The hand corresponding to the side of empyema is put on opposite shoulder, a pillow is put under the last ribs of the healthy side along axillary line. The position must be comfortable, widen the intercostal spaces and allow the pus to drop in the costo-diaphragmatic angle by gravity.

Anesthesia—Local anesthesia must be employed in all cases. We use our novocaine (1 to 300) adrenalin, caffeine solution prepared immediately before the operation.

Incision—Length three to six c.m., according to thickness of thoracic wall, parallel and close to upper border of rib when only intercostal space is opened; when a rib is resected, the incision is carried down to the rib at an even distance between upper and lower borders. When rib or pleura is exposed inject them with more anesthetic solution, and, while waiting for complete anesthesia, place two purse-string sutures made with chronic catgut No: 2 or 3, each suture commencing and finishing at an opposite angle (Fig. 2). These sutures must include all soft tissues except the skin and are to be tied later. During inspiration (Fig. 10) open pleura parallel to rib for about one and a half cm. and introduce the cannula, which I have devised. When a rib has been resected, incise posterior layer of periosteum and pleura in the middle line parallel to the borders of the rib. In this way injury to the blood vessels will be positively prevented.

Empyema cannula—This special cannula is made of thin nickel plated metal and is composed of two halves which fit snugly into each other and form an oval channel (Fig. 3). Each half has two flanges, one short (Fig. 3b) and roundish, another long and flat (Fig 3b). The upper half (Fig. 3b) is provided with two points near the long flat flange and the edges between the flanges form two ridges. The lower half (Fig. 3b) is provided with eyelets, a large ring (Fig. 3) and its edges form two grooves. When the two halves are put together the ridges and the points of the upper valve fit into the grooves and the eyelets of the lower half (Fig. 3). Between the upper part of the ring, which is part of the lower half, and flat flange of the upper half, there is a space which allows the insertion of a rubber valve (Fig. 3). The ring is covered with a cap that is secured in place by a slot (Fig. 3) which fits into a notch found on the ring. This cap ends with a short metal tube to which is attached a rubber tube, the other end of which is put in a bottle.

Insertion of the cannula—The insertion must be done as rapidly as possible, without attempts to evacuate the pus. The lower valve is introduced first. Hold the long flange between the index and thumb, introduce the short flange and push the cannula in with a slight upward turning-in movement (Figs. 4 and 7) until the short flange has turned around the rib and entered the pleural cavity. Then take hold of the upper half, lower slightly the lower half, introduce the short flnage by applying the ridge of the upper half within the groove of the lower half (Fig. 5) and make it slide into the pleural cavity over ridge of lower half by downward movement.

When the short flange has entered the pleural cavity, put the two halves together by inserting the points of the upper half into the eyelets of the lower half (Figs. 6 and 7). Introduce immediately rubber valve (Fig. 12) into space found between the long flange of the upper half and the ring. Now you may proceed slowly, the pleural cavity being closed, you need not fear collapse of the patient. See that rubber valve is raised up and falls back at each respiration, allowing some pus to escape. Apply cap (Fig. 12) to ring of lower half of cannula, securing it in place by introducing little notch found in the ring into groove found in the cap. Tighten and knot the two pursestring sutures, close skin around cannula with silkworm sutures; apply around long flange of the cannula some gauze saturated with thick zinc oxide ointment made with thirty per cent. lanoline, so as to make the cannula fit snugly and become airtight or, still better, gauze impregnated with collodion. (Fig. 8). Put over the site of operation a thick dressing, attach a bottle to the rubber tube and secure the bottle according to circumstances; that is, in such a way that pus can drain into it, when patient is in bed or when patient gets up and goes about carrying his bottle (Fig. 13).

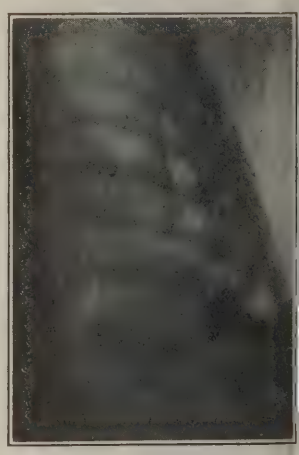

FIG. 14.—Same, ten days after operation. Patient discharged cured nineteen days after operation.

Postoperative care—The patient is allowed to sit up in bed or walk about as early as his condition allows. Many patients have been out of bed the day following the operation. Some patients complain of

pain on the site of operation, which is caused by the compression that the cannula may exercise on the intercostal nerve. The pain, however, is never very severe and is easily controlled with morphine and disappears within twenty-four hours. The postoperative care of patients treated according to instructions given above is very easy. There is practically no postoperative care, no dressing, no drainage tubes to be changed, no toilet of the skin, no lavage of the pleural cavity, no special position to be given to the patient, no painful medication of any kind—in fact, the only care required is the emptying and cleansing of the bottle that collects the pus. The patient is never disturbed for any reason for several days and generally not until the cannula is removed.

When to remove the cannula—The time for the removal of the cannula depends on the condition of each individual patient. As a general rule we can say that the cannula has to be removed when the lung has expanded and the pleural cavity does not secrete pus any longer. This generally occurs between six and twelve days after the operation. X rays are valuable in establishing the condition of the lung and pleura and should never be omitted, when available. When the cannula is removed one problem concerns the surgeon: Will the wound close too soon and pus collect again in the pleural cavity? Our experience has been that when the lung is well expanded and no appreciable amount of pus comes out through the cannula, the cannula can be removed and the wound allowed to heal without fearing any new collection of pus in the pleural cavity, because the pleural cavity is filled by the lung and the tissues can take care of the microorganisms that are still present in the wound.

However, if the patient is in poor general condition of health, and the surgeon fears that the tissues might not be able to take care of the microorganisms present in the wound, a few threads dipped in melted paraffine (Fig. 14) can be put in the wound and removed one at a time a few days after, when drainage is considered unnecessary. Do not use rubber tubings of any kind, under any circumstances: cure would be indefinitely delayed and complications may set in.

Removal of the cannula—In order to remove the cannula, the process of introduction is reversed. That is, the upper valve is removed first, the lower will then practically fall out by itself. In order to facilitate the removal of the upper valve instead of grasping it with the thumb and index finger it should be grasped with an artery forceps.

POINTS TO BE EMPHASIZED

Small amount of pus draining through cannula—On the second or third day only a few drops of pus drain out. Do not think that the cannula does not functionate; there is no more pus to drain out. Only exceptionally is the cannula occluded. We have noted only one case in which zinc oxide ointment filled the cannula. In this case an intern, without knowing how the cannula was made or functionated, removed the dressing the day after the operation and smeared zinc oxide all around the wound, filling the cannula with the same. The damage was easily repaired by cleaning the cannula and putting in a new rubber valve.

Rubber valve—Do not boil the rubber valve. Boiling makes the rubber too soft. Sterilize rubber valve by placing in tincture of iodine a few minutes.

Pulling on the cannula.—See that the rubber tubing and the dressing do not pull on the cannula. Pulling is easily prevented by strips of adhesive plaster passed like straps over the shoulder, holding up dressing and tubing.

Size of cannula.—Only one size cannula is made. It can be used in children (smallest child treated six months old) as well as in adults. In children a rib is resected, in adults the cannula is placed in the intercostal space, except when this is exceptionally narrow. Cure is so rapid that osteomyelitis has never been observed (nine cases in which ribs were resected). As the thickness of the thoracic wall varies with age and patients, it would be impossible to have cannulas that would fit each case snugly. However, it is extremely easy to make the cannula fit as snugly in a baby as in an adult with thick thoracic wall. The cannula is placed in the thoracic cavity. The deep and skin sutures are tied, as explained above. The two external flanges are pulled outward and the space left between the valve and the skin is filled with gauze impregnated with the ointment already described or plain petrolatum. Long strips of gauze wound around the cannula are ideally suited for this purpose. (Fig. 8b.)

Dressings.—If the cannula has been well surrounded by gauze impregnated with zinc oxide ointment, and the sutures have been properly applied and tied, the dressing remains clean. In case some leakage should take place around the cannula, the dressing can easily be changed without causing any discomfort to the patient.

If the surgeon wishes he can verify how the cannula functionates by removing the cap. He will see that the valve is raised up and pulled back at each respiration.

POINTS OF SUPERIORITY OF THE CANNULA OVER ANY OTHER MEANS EMPLOYED AT PRESENT

1. Operation can be performed in all cases under local anesthesia, so avoiding the dangers inherent to general anesthesia.
2. There is no necessity of rib resection or perforation. Osteomyelitis of the ribs and deformities of the thorax are thus completely prevented.
3. Mortality is greatly reduced.
4. Complete cure is more rapid and obtained in more cases than with any other method.
5. The patient is comfortable immediately after the operation and is never disturbed, made uncomfortable or actually hurt, as happens with any other method of treatment.
6. It is the only method that favors distention of the lung, with the most perfect drainage of the pus.
7. All the complications so common with other methods—chronic empyema, fistulas, dropping of drainage tubes in the pleural cavity, and other similar incidents are completely eliminated.
8. This method of treatment is the cheapest.
9. It is perhaps the only method by which double empyema can be safely operated upon.

(To be continued)

The Treatment of Severe Metabolic Arthritis*

SIDNEY A. TWINCH, M.D., F.A.C.S.
Newark, N. J.

As the treatment of arthritis is one of the most difficult problems which we encounter in medicine it may be well at the outset to mention the various forms in which it may appear, because in examining a case of chronic joint disease the first step is the making of a diagnosis and in order to do this intelligently one must pass in review mentally all the conditions that might possibly be present so as to determine in which category the case belongs. Thus we may ask:

Is it acute or chronic rheumatism? Is it specific? Is it tuberculous? Is it an infection, due to some focus, the chief sources of which are the teeth, tonsils, head sinuses and cavities, gallbladder, appendix, colon? Is it of metabolic origin due to faults in the endocrine system alone? Is it complicated by infection from the colon or elsewhere in the body?

All of these questions should be gone over carefully, one after another, and should be either eliminated or incriminated. Infected teeth should either be filled or extracted. I feel very strongly, however, that in the past there have been a great many good serviceable teeth ruthlessly removed without due and proper consideration; therefore much good judgment should be exercised before subjecting a patient to the loss of these essential organs of mastication. Every orthopedic surgeon has had cases in which the removal of decayed and infected teeth has given brilliant results; on the contrary, we also have all seen patients suffering from chronic joint disease who upon the advice of one of their previous physicians have had all their teeth removed, many of which were sound, and, of course, no material improvement in the patient's condition resulted. The question of pyorrhea requires much careful consideration and good judgment; this affection should be treated by a competent specialist if the teeth are to be saved. In many cases in which there is only a moderate pyorrhea with good drainage, no apparent deleterious systemic effects are noted; on the other hand, I am confident that we have all seen patients in whom one apical abscess has evidently been responsible for serious bone or joint infection, and in which prompt removal of the tooth and cleansing of the abscess has resulted in speedy and complete recovery.

Infected tonsils are better out, unless the physician has sufficient skill and both he and the patient can give the necessary time for a course of treatment that will thoroughly clean up the infected crypts. Personally I prefer enucleation, but I have seen cases in which a tonsillar infection was successfully handled by the conservation method, as proved by the abatement of symptoms and their final disappearance. The small buried tonsil should be removed upon suspicion.

Frontal sinus and antrum disease should be handled by a specialist.

*Read before the Orthopedic Section of the New York Academy of Medicine, December 19, 1924.

Metabolic arthritis is probably the most common form of arthritis occurring in adults and possibly i the least understood. Although this form of diseas is most frequently seen in adults it is by no mean confined to them, but is occasionally seen in childre in all stages of its development. In metaboli arthritis there is the acute active stage and it is dur ing this period that the disease is most amenable t treatment; if the patient receives proper attentio at this time we can therefore give the best prognosis Then comes the subacute or more advanced stag and, finally, the chronic and quiescent stage of de formity, during which there is little or no pain, an little or nothing can be done for the patient, but h is left badly crippled and in many cases almost help less.

As metabolic arthritis is so closely allied to wha the laity call rheumatism—and it is hard to get awa from that term if we are to talk to our patients i language which they can understand—it often re quires a good deal of diagnostic acumen to differen tiate between joints affected with chronic rheumat ism on the one hand and those involved in an ar thitis on the other hand. It is quite possible to have in the same individual, one joint affected wit chronic rheumatism and another joint with arthritis so it is difficult to say just where chronic rheumatism ends and arthritis begins. The term rheumatism ha always been used so loosely that perhaps at the out set these terms ought to be defined. In a brief pa per it is impossible adequately to define or to d justice to a description of the diseases commonl known as acute and chronic rheumatism and arthriti and, therefore, in order as to make ourselves bette understood I must first state the premises upo which these subjects are considered. One canno possibly understand chronic rheumatism unless h has a clear idea of acute rheumatism. In acut rheumatism there are three outstanding features 1, rise in temperature; 2, joint symptoms; 3, aci excretion from the skin (1). In a great many case only the second feature may appear. In acute rheu matism as long as the skin remains acid, the patien should not be considered as well and if this acidity persists he will probably have a relapse, or at leas a prolonged convalescence. In uncomplicated acut articular rheumatism when the patient recovers, th joints return to their normal condition. If there i not a restoration of the joints to their normal con dition, there is some complicating condition, prob ably a focal infection.

Of chronic rheumatism we see little in this coun try and the same is true of gout. This is probabl due to the fact that our houses are better heated In Europe people are accustomed to sitting before an open fire and then going out into a cold hall an in this way they become suddenly chilled. This over heating and sudden chilling of the body interfere with the function of the skin as an excretory organ (1). In this country we see more rheumatism of

FIG. 1.—Case II. Röntgenoscopic view of colon before treatment. The subject shows a partial filling of the right colon. Whether feces and gas were in the right colon before the barium enema was given, or a portion of or all the residue was forced back by the barium enema, I am unable to state. The hepatic flexure is very low.

the focal infection type, probably due to our higher living, the use of less plain food, rapid eating, the consumption of rich foods, more cold storage and so forth.

Endocrine dyscrasia, alone or complicated with focal infection from the colon or elsewhere, is frequently at the bottom of metabolic disorders and therefore this phase of the subject must be given careful attention. We speak of endocrine disorders and blame the endocrine glands for failure to perform their functions of preventing toxemia by keeping the food sweet and in proper condition for assimilation, when in reality the endocrine glands have been working to their utmost capacity, in spite of overwhelming infection from one or more foci.

The taking of the life history of the patient should be thorough and searching, going back to early childhood; for instance, if a patient gives a history of more or less chronic intestinal trouble, whether it be diarrhea, constipation or only occasional gastrointestinal upsets, this will be sufficient to draw the practitioner's attention to the gastrointestinal tract, and in many cases the site of the trouble will be found there. An abdomen which is painful upon moderate pressure needs treatment and, ruling out the acute infections such as appendicitis and cholecystitis, should certainly not be passed over lightly when one is searching for focal infection. The gallbladder should be carefully examined for infection. This does not necessarily mean operation; in the absence of gallstones medical drainage is popular at the present time. In my joint cases due to metabolic disturbance I am making a careful comparative study as to the frequency of gallbladder and colon infections as causes of chronic joint affections and thus far I am much impressed with the far greater frequency of colon infections.

We have the great advantage in colon infections that it is possible to gain direct access to the organ and to wash it out as often as it is necessary. It has been my experience that the colon is very frequently the seat of chronic infection and the direct cause of a large proportion of the cases of chronic arthritis. The colon as an infectious organ should be handled without gloves inasmuch as it causes more infections in bones and joints than all other infective foci combined. For years I have realized the menace of the colon as a source of infection, but the ordinary rectal tube, fifteen inches long and of small calibre was entirely inadequate to cope with the situation. In many of these cases there is atony of the colon and it is that which actually requires treatment. For the time being we must dismiss from our minds the swollen and painful joints and direct our attention to what lies back of this manifestation—the real cause of the disease.

Colonic atony has for years been recognized by the internist as a medical entity and has been treated by drugs and diet with little success, but as far as I have been able to ascertain, the important part played by an atonic colon as an etiological factor in chronic joint disease has not been given much thought. The colon has a muscular coat, the function of which is to keep the waste matter in the intestines moving on. If, owing to improper and rapid eating, the colon gets sluggish and the waste material does not move along properly we are going to have, sooner or later, an impaired organ with the

FIG. 2.—Case II. Röntgenoscopic view shows condition of colon following two weeks daily treatment. Right side ptosis markedly improved; the hepatic flexure and cecum raised; the colon resting in about normal position; a partial transient loop at the splenic flexure, and a loop in the pelvic colon. There still remains an incompetency of the ileocecal valve.

inevitable result, the formation of inflammatory products and toxins. The lining membrane of the colon becomes coated with mucus, fibrin, cocci and other inflammatory products, including eventual bacterial invasion of the mucosa and as a final consequence the muscular coat atrophies. The most effectual way to remove the toxic coating together with the other inflammatory products, from the lining membrane of the colon is by frequent irrigation, and the way to increase the muscular tone is to cause the colon to exercise itself. If we pass a colonic tube of sufficient length and size through the colon we accomplish both these objects. The organ is thoroughly flushed out and as soon as the rubber tube is introduced, the colon at once tries to expel it and thus exercises itself and increases its tone. By repeating this process daily for a sufficient length of time we have a colon with a healthy, active lining membrane free from infection and with a strong muscular coat having a good tone.

After the colon has been thoroughly cleansed and freed from inflammatory products, the Morse wave current may be used; this causes rhythmical contractions and relaxations of the colon. We employ a current that causes eleven contractions a minute.

I use an apparatus in which the shortest tube used is thirty-two inches long and the longest one fifty-seven inches, with calibre up to forty-eight French. Such a tube can be passed through the transverse colon and down the ascending colon to the cecum.

Schellberg (2) describes the importance of the tenia coli muscles. He compares to the muscles of the serpent these longitudinal bands, which are capable of pulling the left colon into loops, thus raising the cecum as high as the hepatic flexure. These muscles are controlled principally by the pelvic nerve. I have taken some röntgenographic views that go far to prove this contention.

Schellberg maintains that the tenia coli muscles act like rubber bands. I am unable to detect at present whether or not it is the stretching of these muscles which causes the greater part of the colon to be drawn over to the left side.

The point of the tube was passed midway across the transverse colon before the left colon began to coil. Then the coiling of the colon caused a sharp angle at the splenic flexure, clamping the tube and pulling the point down low in the pelvis. Further advancement of the tube aided the colon to coil in the left abdomen, where about forty-six inches of colon was reached with the tube. There is no doubt that at this point the cecum could be drained and medicaments applied. However, the procedure was as I have described. The tube was then removed and the patient was allowed to empty the colon from the right side to the left. I intend to make a further investigation of this physiology of the colon.

The colon irrigations should be given daily for the first three or four weeks, after that they should be given at least two irrigations a week. In my experience the patients have made the quickest recovery who have had daily irrigations, in other words the more thorough the mechanical cleansing at short intervals the better the outlook.

The laboratory work is important. After the first irrigation the report of the pathologist helps to determine just what solutions shall be used for the irrigations. An alkaline stool needs an acid solution and an acid stool requires an alkaline solution, while for a spastic colon a colloid silver solution should be used. After a number of irrigations have been given and the colon has been sufficiently cleared of fecal matter, and after the laboratory reports have been received, if there is a low count or absence of Bacillus acidophilus, these germs are implanted in the colon after each irrigation. I feel that this organism is important and that a patient who shows a high acidophilus count (forty per cent. to fifty per cent.) present much more favorable conditions on which to work than one whose feces show few or no acidophilus. The implantation of acidophilus changes the intestinal flora; it has for its purpose the killing off the pyogenic organisms and the prevention of their growth. The Bacillus aerogenous capsulatus, as you know, is really the Welch gas (anerobic) bacillus, which causes fermentation and by increasing the acidophilus these microorganisms appear to be successfully combatted; therefore I have found a low acidophilus count to be an indication for further treatment. In our laboratory we have grown cultures of acidophilus and have found that streptococcus will not grow in a medium where there is a fair amount of acidophilus.

These patients usually have considerable intestinal indigestion as shown by inspection of the stools after irrigation. This condition is simply one of the etiological factors which go to make up the condition of colonic atony. I usually treat these cases with the endocrines thus stimulating the colon to better action by using nature's own products. In treating patients suffering with such a complex condition no symptom is too trivial to be overlooked.

A patient with septic arthritis usually has a low percentage of hemoglobin and a low blood pressure.

These patients also have a low alkaline reserve and therefore as collateral treatment I use colloidal lime and preferably by the intravenous route. Of course lime may be administered by the mouth but in my experience the intravenous method has been much more effective. Iodine is so often deficient in these cases that this drug has been added to the lime and introduced directly into the circulation whenever there was evidence of hypothyroidism.

If there is one thing in my practice that has made a deep impression on me, it is the conviction, that no one ever gets a chronic arthritis unless the general health is at a low grade, nor have I ever seen permanent recovery until the general health has been raised to that degree which would be called health for that individual. So much for the principle and my purpose in bringing this subject before you is to call attention in an especial manner to the atonic colon and terminal ileum as a large cause of that type of ill health which conduces to arthritis, and that since I have had recourse to colonic irrigations, properly administered, together with systemic treatment, my recoveries have been far more frequent than under the old system of looking for and cleaning out suppurating foci.

Death Following the Intravenous Injection of Distilled Water in Mistake for Saline Solution

W. WAYNE BABCOCK, M.D.
Philadelphia, Pa.

Recently, in a local hospital, I ordered an intravenous injection of physiological saline solution containing adrenalin for a patient who had a weak pulse during an abdominal operation. After 125 mils of the solution had entered a vein in the arm, convulsive respiratory movements developed, and the patient ceased breathing and became pulseless. The heart did not respond to massage through the open abdominal wound and through a needle introduced into the heart bits of soft clot were aspirated. After the injection of forty minims of 1:1000 adrenalin solution into the heart, and additional cardiac massage, feeble but rather slow contractions were resumed for a few minutes only, and further cardiac massage and the additional injection of about one hundred minims of adrenalin solution and thirty minims of digalen directly into the left ventricle produced no response.

In the meantime, 550 mils of saline solution with adrenalin, had entered the veins and on incising the external jugular vein and compressing the heart, watery, red blood and small, soft clots were expelled. A chemical examination of the saline solution employed showed no trace of chlorides. We had injected distilled water!

Of the nine flasks in the operating room labeled "salt solution," seven contained no chloride. The pharmacist was in the habit of refilling the stock bottle of concentrated saline without renewing the label, and no salt had, on this occasion, been added to the distilled water in the bottle. A trained observer would have noted the absence of refraction waves as the measured portions of the supposed concentrated solution were added to the flasks of distilled water on the operating floor. But, in this case, dilution had been delegated to an unsupervised pupil nurse.

IMPORTANCE OF PROPER SAFEGUARDS

Impressed by the great danger from ignorance or carelessness in the preparation of solutions for intravenous use, we would urge all hospital authorities to make sure that proper safeguards are used in the institutions they serve.

In some of our better pharmacies, three prescription clerks check each other to avoid error in compounding; such an error as led to the death of one of our best known urologists a few years ago. Possibly there may be other hospitals in which the making of saline, and other surgical solutions, is delegated to a pupil nurse, or to a pharmacist who is not specially instructed or supervised. In our opinion, for the average hospital the slight additional expense of accurately made tablets or ampoules of powder is justified by the reduced liability to error, as compared with extemporized concentrated stock solutions, and it is also our opinion that at least two trained and responsible persons should check the accuracy of all preparations for intravenous administration.

In our patient, other factors—syphilitic aortitis, spinal anesthesia, emotion, and operative shock—must be considered as possible causes of death, but none of these explain the alteration of the blood with multiple clots or emboli in the heart and vessels immediately after the collapse. The chief danger period of spinal anesthesia is from ten to twenty-five minutes after the injection. Here, thirty-five minutes had passed and the patient had reacted from an early circulatory depression, and was given the intravenous injection not because it was absolutely needed, but as a precautionary measure.

REPORT OF CASE

The patient was a fairly well developed colored woman of twenty-eight years, who was admitted for persistent nocturnal attacks of abdominal pain with vomiting, that had been ascribed to cholecystitis, but that probably were due to aortitis. When brought to the operating room, the patient was emotional, and fainted when seated on the operating table, the systolic pressure falling from one hundred and twenty-four to sixty. Six centigrams of stovaine were given through the first lumbar interspace, and ten minims of adrenalin subcutaneously. The systolic pressure soon improved and the pulse rate fell from one hundred and twenty to ninety-eight. Abdominal exploration revealed an imperfectly developed left kidney, a chronic inflammatory disease of the uterine adnexa, with small uterine fibroids and no evidence of disease of the gallbladder. Owing to the fainting of the patient, the operation was somewhat delayed, and thirty-five minutes after the spinal injection during the abdominal hysterectomy, as the patient seemed rather clammy and weak, although the respirations were regular and the pulse better than at the beginning of the operation, a prophylactic intravenous injection of adrenalized saline was ordered.

Five minutes after starting this injection, and after 125 mils of solution containing about five minims of adrenalin had entered the vein, respiratory difficulty and collapse occurred, which did not respond to cardiac massage through the abdomen or chest; or to repeated intracardiac injections and artificial respiration. Examination of the heart shortly after death showed many smooth, yellow plaques lining the coronary arteries and aorta. The anterior coronary artery was nearly occluded. The heart was normal in size, and degeneration of the myocardium or deformity of the valves was not evident. The blood showed marked hemolysis, but gave no Wassermann reaction.

It is true that the reaction from the intravenous injection of a few mils of distilled water is not especially dangerous, but the extensive hemolysis, and tendency to coagulation produced by the injection of large quantities of distilled water may be rapidly fatal.

Recovery has been reported after the intravascu-

lar injection of large amounts of distilled water. But such injections must be considered as very dangerous, especially in a weak patient. Besides the hemolysis produced, distilled water tends to throw the globulin out of solution and to shorten the clotting time, conditions favoring thrombosis and embolism, and consequently sudden death.

2008 WALNUT STREET.

An Efficient Method of Hemostasis Without Suture*

GRANT E. WARD, M.D.

Baltimore, Md.

The success of a surgical operation is dependent on several factors, two of which are despatch, and the rapidity and completeness of hemostasis. Surgeons the world over are constantly striving to improve their technic so as to reduce the time factor and to effect complete and permanent hemostasis.

Recently we have used the endotherm knife (needle), to replace the scalpel in opening abdomens and in removing breasts, even doing a complete breast operation without once picking up the surgeon's knife. This new needle cutting method (acusection) has proved useful in stopping capillary and skin oozing and in sealing the lymphatics; larger bloodvessels which bleed freely are caught with forceps and then coagulated with bipolar endothermy in place of a ligature; this is done by switching the machine from the undamped high frequency acusection current (endotherm cutting needle) to the damped high frequency coagulating current which continues to pass through the same electrode. The original technic for checking hemorrhage then was to stick the needle electrode into the tissue at one or more points around the end of the hemostat and to hold it there until the tissues were coagulated and the bleeding checked.

While I was thus engaged following a radical amputation of the breast the electrode happened to touch the clamp itself and caused a spark at the point of contact. This gave me the idea of running the current down the clamp and in this way concentrating it more directly on the bleeding vessel and on it alone. I tried it out and at once noted a neater area of electrocoagulation and less injury to the surrounding tissues than by the previous technic. This therefore appears to me to be an ideal method of hemostasis, except in large vessels.

TECHNIC

The technic is simple (Fig. 1). The operator grasps the clamp on the vessel in his left hand and holds it at right angles to the surface and clear of all contact with the body except at the tip where the vessel is caught. With the right hand the active electrode (needle) touches the hemostat at any convenient point and remains a fraction of a second or longer when a small ring of electrocoagulation forms at the end of the instrument, which is now removed. There is no after bleeding and the small area of coagulation is soon absorbed without slough or hemorrhage.

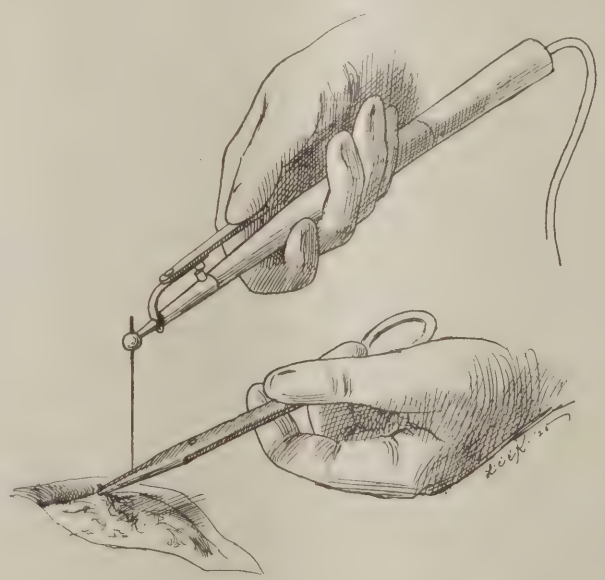

FIG. 1.—The figure illustrates the technic of hemostasis without ligature. The clamp grasping the cut vessel is held in the left hand. Holding the electrode in the right hand, the clamp is touched at a convenient point; the current then runs down to the vessel, which it coagulates. In this illustration the vessel is made a little more prominent than usual; the method is efficient, however, even though the vessel may be situated quite deeply in the tissues.

WARNINGS

1. Be careful not to touch any other part of the patient with the hand holding the clamp to be electrified, thereby avoiding a short circuit which would burn patient or operator.

2. In checking bleeding from primary branches of large vessels such as the axillary artery or vein the coagulation should be done at a distance from the larger trunk. If this is not observed, injury may occur sufficient to cause a secondary hemorrhage, or the current may coagulate the blood contained within the larger vessel, possibly partially occluding its lumen.

ADVANTAGES

1. With this method few ligatures are needed. One half or one third the time is required to lift the clamp in one hand and touch it with the active electrode (needle) in the other than to tie off the vessel (using two or three knots) and cut the ligature.

2. It is easy to realize the great saving in ligature material with this method of hemostasis—no mean factor in the economy of the operating room.

3. Less foreign material is left in the wound by the coagulating method of hemostasis than by the ligating technic. Certainly a little coagulated tissue is easier to absorb than ligature material. Per primam healing is not hindered.

The Problem of Gastric Cancer*

S. WENDKOS, M.D.

Philadelphia

In June, 1924, Dr. H. A. Christian, of the Harvard Medical School, read a paper at the meeting of the Association of American Physicians entitled Some Observations, Largely Pessimistic, on Early Diagnosis of Cancer of the Stomach. He made a startling statement to the effect that we had made no progress in the diagnosis and treatment of cancer of the stomach, and that even the x ray had been of no help.

When I read this article I was startled, not because of disagreement, but because I found confirmation, from an authoritative source, of a conviction that had been growing upon me for the past two years. Dr. Christian said that all patients admitted on his service at the Massachusetts General Hospital presented no difficulty in the diagnosis of cancer of the stomach. They either came in with a ready diagnosis or the interns made the same from a clinical examination on admission. The x ray was of no help in disclosing unsuspected cancer. All these cases were suspected clinically and most of them were diagnosed without the help of the x ray.

Soon after my return from visiting the Mayo Clinic and several other clinics, I published a paper in which I discussed the problems of gastroenterology. One of the problems for which I sought a solution was that of the early recognition of cancer. I formulated a routine examination for my own enlightenment and I hoped to be able to detect early cancer of the stomach. But unfortunately my series of some fifty cancer cases which I examined in the past eighteen months disappointed me. Most of them were referred to me with either a ready diagnosis or a suspected one, and upon examination all of them proved to be late and inoperable cases. My examination corroborated the family doctor's suspicion or knowledge of the existence of malignancy.

The problem then of gastric cancer is early diagnosis. The following questions present themselves:

1. How can we make the potential cancer patient consult his physician earlier?
2. How should the family physician be guided in recognizing or suspecting malignancy?
3. How early should we bring to bear all our newest methods of examination and diagnosis?
4. On what evidence should the patients be exposed to surgery?

EARLY DIAGNOSIS

It is unquestionably true that cancer patients enter a hospital too late; that they consult the röntgenologist or the stomach specialist too late also. Who is to be blamed for it? The general practitioner? No; at least not entirely. I find from experience that the general practitioner who refers a case to me, for instance, is not always the first one consulted by the patient. He may be the third or the fourth. I feel sure that the general practitioner of today is sufficiently familiar with the problem to suggest a study of a particular case in which the patient presents himself with gastric pain and vomiting, during the cancer stage. On the other hand, it is quite likely that the patient comes to the physician for a cursory examination and a prescription after ignoring his symptoms for a long time, entirely ignorant of or rejecting the idea of the consulting physician that there may lurk some danger in the apparently vague symptoms. The patient still looks well, having lost no weight, and is still attending to business. The same patient, not feeling better, in a few days consults another physician; tells him what the first one suspected and even denies that he vomits or has other cardinal symptoms.

The second doctor, sensing the patient's attitude and wishing to quiet his fears, prescribes a mixture of bismuth with morphine or codeine, and calls the disease indigestion, or gas in the stomach. The patient goes away lulled into the belief that there is nothing wrong with him. The codeine or morphine or limited diet relieves him for awhile and he comes again to the doctor exultingly and informs him that he feels fine, except, that once, after partaking of some fish or a tiny piece of chicken the night before, he vomited; otherwise, he feels fine. The physician hates to disillusion him and tells him not to eat chicken, and gives him some other medicine without morphine or codeine. Next day he gets a hurried call to see the patient, who is very sick; he cannot eat, he vomits, and has pain. The whole family is thoroughly alarmed, the neighbors offer their help, suggesting this doctor or that doctor, or they may even suggest calling in a specialist. The specialist is called, and seeing the excitement of the family, he quiets their fears and prescribes five drops of nux vomica and ten drops of dilute hydrochloric acid.

On the following day the first practitioner is called back and after listening to the whole story, with chest swelling at his own superior knowledge, he suggests that the patient go to a specialist's office, who will study his condition from every angle, and then decide what should be done. Thus the patient, after wasting two or three months, lands at the hospital or at the specialist's office.

I hope you do not consider this picture, which is drawn from personal experience in the last few years, an exaggerated one. I am sure all of you can duplicate it. The family doctor who wishes to retain his patients is afraid to breathe the word "cancer."

The problem of gastric cancer reminds me of the problem of tuberculosis some twenty or twenty-five years ago. Then, too, both physician and patient were afraid of the diagnosis of tuberculosis because it seemed so hopeless, and the patient was treated for chronic bronchitis for years. But with the dawn of the twentieth century medical and lay propaganda,

*Read as part of a symposium on cancer, during cancer week, before the Southeast Branch of the Philadelphia Medical Society, November 6, 1924.

carried on by the chest specialists and sanatoria, spread the gospel of the curability of tuberculosis, provided it was recognized early.

In our eagerness to make early diagnosis we must be willing to make mistakes for the sake of safety. In tuberculosis certain incipient and even preincipient stages are recognized and the physician who makes the diagnosis, even of the incipient stage, does not hesitate to remove the patient from his occupation, whatever it may be, and give him the benefit of a cure. We must forget the textbook picture of cancer of the stomach,—that picture of cachexia, pain, vomiting, loss of weight, and a palpable tumor. What horrors it brings up! Only then will we begin to recognize early cases.

THE RECOGNITION OF MALIGNANCY

The second question which will now be discussed is most difficult to answer; but a few suggestions that have aided me may also be of some help to you. The answer will be in the form of specific cases that came to my notice.

When a man, a hard working laborer, or a business man, always in good health, begins to complain a little of his stomach, at the age of forty or over, suspect cancer until you are able to rule it out definitely. I know of two patients during the past six months who were expressmen by occupation. One patient will tell you that previously he could eat and digest leather; but now his appetite is poor, he vomits occasionally, but does not lose weight. Such a patient should be subjected to a thorough examination. This advice may seem selfevident but I know that for weeks or months such patients are being treated in the dark without an examination. Do not feed them with medicine and do not make yourself ridiculous by telling them that it is gas or indigestion. Subject them to a thorough examination, even if you have to frighten them. You must take the bull by the horns. If you lose one patient because of frightening him, you may gain others because you understood the gravity of their condition much sooner than others.

THOROUGH EXAMINATION

In examining such patients do not be satisfied with half measures. I know of a case in which the general practitioner tried to do his best by referring his patient early to a supposed specialist. The latter passed a tube, found an achylia and treated the patient for weeks and months for anacidity by lavage and dieting. Three months later a surgeon was consulted and thought he felt a mass and suggested an x ray. The patient then came to me. It was now easy to establish by any method the far advanced condition of the cancer. This patient, I felt, was sacrificed by our halfhearted methods, our egotism, and our proprietary rights in our patients. Is it necessary to emphasize that achylia in a person heretofore healthy is of great significance? I do not say it is pathognomonic but it should point to the need of a thorough examination by all the methods at our disposal. Another patient may come to you complaining of lost appetite, looking rather thin, and giving a history of cramps and a burning sensation in the epigastrium for several years. He had been treated for disease of the stomach for fifteen or twenty years, but lately he had lost his appetite completely, particularly for meats, and vomited occasionally, which he had not done before. In a case like this, after you have gone more thoroughly into the history you will not be far wrong in suspecting an old gastric ulcer with, perhaps, some malignant change.

Needless to say no tonics or stomachics should be given before a thorough examination is made. While the percentage of gastric cancer ingrafted on an old ulcer has been reduced, according to recent statistics, and although some authorities even deny such occurrences, the physician undertaking to treat such a patient should have a clear idea underlying the symptoms. A simple stricture of an old pyloric ulcer may produce the above mentioned symptoms. But an x ray study will differentiate a benign stricture of a healed ulcer from malignant obstruction. The prognosis would be radically different in the two cases and without a thorough investigation it is impossible to tell which is which.

MASKED MALIGNANCY

Still another patient may come to your office, a person with a definite history of tuberculosis, with some of its classical signs, and when the gastric symptoms predominate we should not omit an investigation. Two such cases came to my knowledge recently, in which malignancy developed but was ignored for months on account of the pulmonary condition.

A woman may consult you and complain of vomiting and anorexia. She tells you that she has repeated attacks of gallbladder trouble with signs pointing to the presence of gallstones. Do not be too easily satisfied that this woman is suffering from cholelithiasis only. You may be surprised to find malignancy of the lower end of the esophagus, or of the gallbladder or even primarily of the stomach, or quite often a malignancy of the liver.

And still another patient may come to you complaining of constipation and slight pain in either groin—something which he has never had before; he always had a regular stomach, had already tried to physic and even diet himself. He feels somewhat weak. Or, he may tell you that he is constipated for a few days—feels full and then has a loose bowel movement with or without blood, with or without mucus. Don't add insult to injury by prescribing some of your favorite mixtures but make a study of his colon first.

These suggestions and don'ts may seem to you too selfevident, but I can assure you that I come across their infraction and meet instances almost daily of their being ignored by the general practitioner. We sin more by omission than by commission.

Now suppose you follow my advice and in your overanxiety examine your suspected patients without loss of time, on your part, say a dozen a year, and in ten you get negative reports, and only in two are your suspicions of early malignancy confirmed, either in the stomach, or the cecum, or the sigmoid —think what a gain it would be if every doctor would be able to do that. Out of fifty or sixty thousand patients who die annually we might thus save a considerable number, by the application of the knife early, which is the only curative method.

I have not given a description of the full symptomatology of cancer of the stomach, simply because I want you to recognize the early cases that come to your notice with only one or two symptoms and no more. The typical inoperable case is too clear and is easily diagnosed.

SIGNS TO AID IN EARLY DIAGNOSIS

The next question is, What signs should guide the diagnostician in making a diagnosis of early cancer? On his shoulders rests a tremendous responsibility, but no more than on the tuberculosis specialist who will interrupt a young person's career, by not taking any chances with an incipient or a preincipient stage of tuberculosis.

THOROUGH X RAY EXAMINATION ESSENTIAL

We assume that a thorough clinical examination of a particular case under discussion will exclude kidney disease, diabetes, heart disease, syphilis, pernicious anemia, and tuberculosis as being the cause of the vomiting and pain, and that the symptoms are entirely focused in the gastrointestinal tract. The physical examination should be followed without delay by an x ray examination and this should be as thorough as possible. The routine should include esophagus, stomach, colon, appendix and the gallbladder. The röntgenologist too often does what is specifically asked for by the referring physician. When a patient is referred for an x ray of the stomach or the gallbladder, they do that and nothing else. A recent case may illustrate what I mean. A person was studied in a well known hospital in this city and the patient, perhaps not making herself clearly understood, pointed to her epigastrium. The stomach was x rayed and found negative. She left the hospital and landed in another hospital, where further study was made and the gallbladder x rayed and no more. A pathological gallbladder was found and an attempt to pass a duodenal tube for the purpose of drainage was unsuccessful on several occasions. Finally the patient was fluoroscoped with the tube in the esophagus and we found an obstructive lesion of the lower end, most likely carcinomatous.

The best opinion of the most prominent x ray specialists in the country is that irrespective of what is asked for, a patient should be rayed from mouth to rectum in arriving at a diagnosis of a gastrointestinal condition.

PYLORIC INVOLVEMENT

Lesions of the pylorus are the earliest to diagnose from the röntgenological point of view. Clinically, also, these types produce the earliest symptoms. At the earliest time there will be a dilatation of the stomach with consequent retention of the barium meal after six hours; rapid emptying of the stomach in the absence of an ulcer history will indicate infiltration of the pylorus and causing it to gape. A filling defect, slight or marked at or near the pylorus, should also signify early malignancy, especially in the absence of an ulcer history. Roughly speaking, a little over fifty per cent. of the cases of cancer of the stomach occur at this point. More difficult are those situated on the lesser curvature of the anterior or posterior wall; but even here chronic ulcers can be diagnosed.

Sometimes, however, we find no lesion present within the stomach to explain the symptoms, yet by a sense of intuition, we may look through and beyond the stomach and locate the early lesion in the head of the pancreas. The most hopeful cases, then, are those with lesions of the pylorus or gastric antrum. And these being easiest of recognition are therefore susceptible to early treatment by surgery. In the trinity of diagnostic methods of early cancer last but not least comes gastric analysis. If achylia is present we are strengthened in our suspicion of malignancy, but the presence of free hydrochloric acid should not deter us from making a diagnosis. Dr. Friedenwald in one hundred cases of malignancy of the stomach found normal acidity in twenty-six per cent.; in six per cent. even a hyperacidity, and only in fifty-two per cent. was an absence of hydrochloric acid found. In several of my own cases the presence of the normal acidity did not deter me from making a diagnosis of cancer.

Now suppose the stomach is really negative to suggestive signs of malignancy, examination should be repeated at short intervals, if the clinical signs persist. During the cancer stage a definite indication of a gallbladder condition or chronic disease of the appendix should be subjected to operative procedure. Thus can the patients not only be cured of their symptoms, but an attempt made definitely to exclude malignancy.

PREVENTION OF CANCER

A consideration of the problem of gastric carcinoma cannot be complete without a due consideration of the phase of prevention. At an international conference of health problems Sir Arbuthnot Lane has said that cancer is the result of chronic poisoning of the tissues of the body, and in a vast majority of cases by the poisons absorbed from the gastrointestinal tract. Our only hope of preventing cancer is by obviating the development of chronic intestinal states in all its manifestations and results. Cancer is one of the consequences of stasis. Prevention of cancer can be brought about by a complete revolution in our diets and habits. In a discussion of this subject Noguchi said: "I cannot see any reason why various substances and local irritations due to abnormal alimentation cannot likewise produce cancer in the human body which is undoubtedly far more susceptible to these noxious substances than average animals." John B. Deaver, in an article on carcinoma of the gallbladder said: "If, as most authorities believe, gallstones are the most exciting factors in the development of cancer, it would seem that here one is forunately dealing with a demonstrable precancerous disease which can be efficiently eradicated by the removal of the benign disorder known as cholelithiasis." A. Leitch concludes from extensive observation and experiments that gallstones are capable of causing cancer of the gallbladder.

I have compared this problem to that of early tuberculosis in former years. The following extract would suggest the further analogy as to its control.

H. Charles maintains that in order to control

cancer incidence it should be made a notifiable disease and that cancer patients be segregated, first, in the cause of the unfortunate sufferers and to allay the growing fears of the community as to the nature of the disease (infectious or contagious), and secondly, that treatment may be given and experiments and research made under the best conditions.

CAUSE OF CANCER

I have not touched upon the cause of cancer. I only want to point out a curious coincidence that appealed to me while looking up this subject. The gastrointestinal tract, besides being enervated by the pneumogastric and the autonomic nervous system has also certain neuronodes situated at different points along the gastrointestinal tract, and Keith, their discoverer, points out their location as being in the upper part of the esophagus, at the cardiac end, in the duodenum near the ampula of Vater; in the cecum, in the sigmoid and in the lower rectum. I simply want to call your attention to the fact that it is precisely in these localities that cancer is found. Perhaps Lane is right in believing that constant irritation from the gastrointestinal tract is the cause of cancer in these regions, but I leave that thought with you for further consideration.

Visualization of the Gallbladder With Sodium Tetrabromphenolphthalein by Oral or Intraduodenal Administration Through the Duodenal Tube*

I. O. PALEFSKI, M.D.
New York

The ensuing ill effects following the use of the sodium tetrabromphenolphthalein as described by Graham Cole and Capher (1) render the intravenous route impracticable for clinical purposes. The intolerance by the rectum for solutions of this salt have been emphasized by these investigators. It therefore occurred to us to test the intestinal tract and, as a result of our observations, we now can definitely state that this route is adaptable for visualization of the gallbladder.

No toxic effects have ever been observed after the introduction of this essentially irritative salt into the intestines and after its slow absorption into the circulation. It appears in the normal gallbladder two to four hours later with increasing quantity to the fifteenth and twentieth hours (Fig. 1) and is entirely out at the end of thirty hours. The technic is as follows:

Fig. 1.—Visualization of the gallbladder in patient J. M. Harlem Hospital. Dense shadow of normal gallbladder obtained eighteen hours after the injection of sodium tetrabromphenolphthalein into the duodenum. This shadow was visualized only between the second and twentieth hour.

TECHNIC

For intraduodenal administration our duodenal tube is introduced on the fasting stomach about 8 a.m. and allowed to pass into the second or preferably the third part of the duodenum. An eight-ounce emulsion of acacia, in which there have been incorporated, depending upon the size of the patient, thirty to sixty grains of sodium tetrabromphenolphthalein, is then injected through the tube and the latter is removed. About thirty minutes preceding this a hypodermic injection of one sixth grain of morphine sulphate and one one hundredth grain of atropine sulphate is given to counteract the resultant nausea, increased intestinal peristalsis and the desire to move the bowels.

Exposures of the gallbladder region are taken, employing for the purpose the established x ray technic and two, four, fifteen, twenty, twenty-five and thirty-hour films are obtained, to determine the patency of the biliary ducts and the degree of filling of the gallbladder. Cathartics and enemas are withheld for thirty hours. For the oral administration of the salt, the patient is given fifteen salol coated pills, each containing five grains of the salt, on the fasting stomach with aid of cold water to start gastric peristalsis. The oral method, so far, has not proved as efficacious as the intraduodenal. The gallbladder shadows obtained after the latter method are distinct and offer an opportunity to study the pathology of the biliary ducts and gallbladder.

*This technic was developed at the Harlem Hospital with the assistance of Dr. P. Kleinkopf, resident physician, and with the kindly cooperation of the staff of the x ray department.

Practical Therapeutics

TRYPARSAMIDE IN NEUROSYPHILIS*

HERMAN P. HYDER, M.D.
Washington, D. C.

Since tryparsamide was introduced as a therapeutic agent, there has been quite a little speculation concerning its value. The results obtained by the various investigators strongly suggest that, when used discreetly, tryparsamide will be of much value in the treatment of trypanosomiasis, whether in the human or animal, and that it has a therapeutic use in certain forms of syphilis. At present we are more interested in its use in syphilis, especially neurosyphilis.

The drug was first synthesized by Jacobs and Heidelberger, and its biological action was studied by Brown and Pearce in 1915, but no systematic clinical investigation was begun until late in 1919. As a spirocheticide, tryparsamide was rated far below the other arsenicals. Brown and Pearce say, "The consideration that led to the selection of this drug for the treatment of these diseases may be divided into three groups. First, action on the animal organism: Second, action on animals infected with trypanosomes and spirochetes; and third, certain facts relating to the biology of syphilitic infections, and the part played by animal resistance in determining the course of this disease." Tryparsamide causes but little irritation when introduced subcutaneously, and it has a stimulative effect which exerts a favorable influence on the disease out of proportion to its spirocheticidal action. The results obtained by Brown and Pearce with syphilis in rabbits led to the prediction that tryparsamide would be of little value in the treatment of early syphilis where the sole purpose of treatment is directed toward rendering sterile the infected person.

Thus, in early syphilis, tryparsamide is not seriously considered as a routine treatment when the powerful arsphenamine group is at our disposal.

The results obtained by Lorenz and his coworkers in the treatment of neurosyphilis, especially in general paresis, aroused much interest. They reported in paresis the arrest of the disease in about sixty-three per cent. of their cases, improvement in about fifteen per cent., and no improvement in about twenty-two per cent., while in meningovascular neurosyphilis they reported ninety per cent. as arrested and ten per cent. improved. The reports of Moore and his associates have borne out the above experience, as their results were almost identical. With the limited number of cases at our disposal our present observations are not very different from the foregoing. In the report of Solomon and Veits the results obtained were not far superior to those of the older drugs used in the treatment of neurosyphilis.

The most important thing in selecting cases for patient. In the selection of patients for treatment, any form of treatment is the clinical condition of the just as is the case in the introduction of new drugs and new methods of treatment, we encounter the element of personal equation, which must be dealt with, and, of course, the serological side as well as the clinical aspect should receive due consideration and the two correlated. Lorenz and his associates, and Moore and his associates reported their experience with tryparsamide on a percentage basis, while Solomon and Veits gave their results by the method of comparison.

I shall now endeavor to present a brief summary of a number of cases, selected more or less at random from the hospital records:

CASE I.—A white male, aged forty-eight, with typical general paresis, was admitted to this hospital in January, 1921. He was in poor mental and physical condition when admitted. He showed loss of memory and was unable to walk unassisted. He received considerable other treatment for two and a half years when he was placed on tryparsamide in July, 1923. He received thirty-one injections of tryparsamide intravenously, and took mercury by inunction. July 7, 1923. Before treatment was begun, his serology was as follows:

Wassermann, blood,	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	13
Gold sol.	5555432100.

Eleven treatments were given with the following readings on September 19, 1923:

Wassermann, blood	4 plus
Wassermann, spinal fluid,	Neg. singles, 4 plus in other diluions
Globulin	4 plus
Cells per c.mm.	8
Gold sol.	5555543210.

Ten treatments were given with the following results on January 23, 1924:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	6
Gold sol.	5554321000

He was again given ten treatments and his serology was taken on September 4, 1924, and was as follows:

Wassermann, blood	Neg.
Wassermann spinal fluid,	Neg. in singles, 4 plus in other dilutions
Globulin	Neg.
Cells per c.mm.	4
Gold sol.	5554321000.

The treatments seemed to shake this patient up considerably, but as soon as they were discontinued he would recuperate. He is not very different from what he was four years ago. He still has a clear mentality though he suffers from motor incoordination and marked speech defect. It may be said that this patient appeared to be an unfavorable case for any kind of treatment.

CASE II.—This patient was a white male, aged thirty-three. He came to this hospital in an excited and disturbed mental state, despondent and confused with the clinical manifestation indicative of paresis, with the following serology, taken June 6, 1923:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells, per c.mm.	37
Gold sol.	5555543210.

*This paper will be read before the American Congress on Internal Medicine, March 9 to 14, 1925, at Washington, D. C.

After ten treatments of tryparsamide his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	8
Gold sol.	5555430000.

Without further treatment his serology was taken January 16, 1924:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	16
Gold sol.	5555432000.

He was given another series of ten treatments, with the following serology, November 13, 1924:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	5
Gold sol.	5555432000.

The patient received tryparsamide alone and failed to show any response clinically.

Case III.—This patient was thirty-three years old when he came to us with a diagnosis of cerebral lues. He showed the typical reaction of dementia precox imposed on defective mentality. Ht was in rather poor condition physically, before being placed on treatment. He showed the following serology May 31, 1923:

Wassermann, blood	2 plus
Wassermann, spinal fluid	2 plus
Globulin	Neg.
Cells per c.mm.	19
Gold sol.	1224210000.

After taking ten treatments of tryparsamide, his serology was as follows, September 19, 1923:

Wassermann, blood	Neg.
Wassermann, spinal fluid	2 plus
Globulin	Neg.
Cells per c.mm.	3
Gold sol.	Normal curve

Without further treatment, on January 16, 1924, his serology was as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid	2 plus
Globulin	Neg.
Cells per c.mm.	3
Gold sol.	Normal curve

He was given ten additional treatments and on November 15, 1924, the results were as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid	Neg.
Globulin	Neg.
Cells per c.mm.	4
Gold sol.	Normal curve

This patent had no other treatment in connection with tryparsamide. He has improved much physically though his mentality has responded slowly.

Case IV.—This is a white male patient, aged twenty-six. His case was diagnosed as general paresis, and he was described on admission as profoundly disoriented, dull, apathetic, seclusive, confused, mute and uncleanly. Left knee reflex more marked than right. General physical condition fair. On January 16, 1923, his serology was as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid	4 plus
Globulin	2 plus
Cells per c.mm.	49
Gold sol.	5554321000.

After being given ten treatments of tryparsamide, his serology was as follows, on September 19, 1923:

Wassermann, blood	Neg.
Wassermann, spinal fluid, Neg. singles; 2 plus, doubles; 4 plus quadruples.	
Globulin	Neg.
Cells per c.mm.	2
Gold sol.	Normal curve

On January 16, 1924, without further treatment, his serology was as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid	2 plus
Globulin	Neg.
Cells per c.mm.	2
Gold sol.	Normal curve

He was given ten additional treatments of tryparsamide, and showed the following on November 13, 1924:

Wassermann, blood	Neg.
Wassermann, spinal fluid, Neg., singles and doubles; 1 plus, quadruples.	
Globulin	Neg.
Cells per c.mm.	0
Gold sol.	0111000000.

This patient has shown no change clinically.

Case V.—This patient was twenty-six years old when admitted to this hospital, was resentful at the idea of being locked up, showed great psychomotor activity, giving the clinical symptoms of paresis. The serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	2 plus
Cells per c.mm.	23
Gold sol.	5555542100.

After ten treatments of tryparsamide were given, on September 19, 1923, the results were as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid	3 plus
Globulin	2 plus
Cells per c.mm.	10
Gold sol.	5544300000.

The second course of treatments were discontinued after the seventh injection, because in the patient there developed psychic vomiting at the time each treatment was given. No mercury was given this patient, and but little improvement was noted clinically. The last serology, on November 5, 1924, was as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid	Neg.
Globulin	3 plus
Cells per c.mm.	1
Gold sol.	5444332100.

Case VI.—This patient was thirty four years old when admitted to this hospital, giving a history of chancre in 1911 and showing clinical manifestations of paresis. He gave the impression of being in the advanced stage, and he was in a rather poor condition physically. His serology was as follows on October 24, 1923:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	40
Gold sol.	5555432100.

He had eight treatments of tryparsamide in conjunction with nine injections of salicylate of mercury and on March 5, 1923, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	plus
Cells per c.mm.	4
Gold sol.	5554320000.

This patient died a few weeks after treatment was completed.

Case VII.—This patient was fifty-four years of age when admitted. He was noisy, disturbed and destructive, and quite belligerent. He gave a history of syphilitic infection, but could not give the date when it occurred. He was somewhat undernourished. His serology was as follows on May 15, 1923:

Wassermann, blood	Neg.
Wassermann, spinal fluid	4 plus
Globulin	plus
Cells per c.mm.	17
Gold sol.	3334443210.

He was given eight treatments of tryparsamide and on September 19, 1923, his serology was as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid,	Neg. singles; 4 plus in doubles and quadruples.
Globulin	plus
Cells per c.mm.	5
Gold sol.	0012210000.

Now he was given nine treatments of tryparsamide, with serology as follows, January 24, 1924:

Wassermann, blood	Neg.
Wassermann, spinal fluid	4 plus
Globulin	plus
Cells per c.mm.	3
Gold sol.	0002210000.

This patient left the hospital shortly after the last course of treatments was completed. He was in excellent condition clinically. He had mercury by inunction while he was taking tryparsamide. His diagnosis was cerebral syphilis.

Case VIII.—The patient was admitted to this hospital on October 20, 1923, giving his age as forty-three years. He gave a history of chancre twenty-five years previously. He gave a clinical picture of general paresis, agitated type. On October 24, 1923, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	68
Gold sol.	5555432100.

He received eight treatments of tryparsamide, and nine injections of mercury, over a period of eight weeks, and on March 12, 1924, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	6
Gold sol.	5555542000.

He now received ten treatments of tryparsamide without mercury and, on November 20, 1924, his serology was as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	11
Gold sol.	5554321000.

The patient has quieted down mentally and is enjoying good health physically.

Case IX.—Diagnosis, cerebral syphilis. Admitted November 21, 1922, aged twenty years. He was nervous and excited and inclined to be argumentative. Vision of right eye grossly impaired due to optic atrophy; external strabismus of same eye due to impairment of internal rectus; speech defect present. Shows some general muscular incoordination. Fairly well nourished. He had considerable treatment before being placed on tryparsamide with but little improvement. On June 6, 1923, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	310
Gold sol.	22333443100.

He received ten treatments of tryparsamide, and, on September 19, 1923, showed the following:

Wassermann, blood	4 plus
Wassermann, spinal fluid	Neg.
Globulin	plus
Cells per c.mm.	15
Gold sol.	0022210000.

Without further treatment, his serology on January 16, 1924, was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid	3 plus
Globulin	Neg.
Cells per c.mm.	9
Gold sol.	Normal curve

He was again put on treatment, receiving eleven injections of tryparsamide and, on November 20, 1924, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid,	Neg. in singles and doubles; 1 plus in quadruples.
Globulin	Neg.
Cells per c.mm.	6
Gold sol.	Normal curve

This patient was given twenty-one treatments of tryparsamide; no mercury was given. He has improved very much clinically and at present appears to be capable of taking care of himself from a mental standpoint.

(*To be continued*)

THE BASIS AND DEVELOPMENT OF A SYSTEMATIC RESPIRATORY THERAPY

Ludwig Hofbauer, M.D.

Vienna, Austria

(*Concluded from page 412*)

Etiological respiratory therapy should also include those cases in which the surgical treatment combats the cause of all the changes and, therefore, the results can be eliminated only postoperatively by a return to the normal respiratory mechanism. The following may be mentioned as examples:

1. The pathological changes in the respiratory apparatus developing from nasal obstruction by polyps, enlarged turbinates, bronchitis, atelectasis, asthma and socalled predisposition to tuberculosis, which must be considered as the results of continued mouth breathing. They usually do not disappear if operation is considered to be sufficient, or if the patient insists upon using the nasal air passage after the removal of the obstruction.

2. Pleural emphysema, of which the associated symptoms of disease are flattening of the thoracic cage, scoliosis, drooping shoulders, atalectasis formation, a tendency toward catarrh, and tuberculinization. These do not disappear after mere removal of the pus and, similarly, the suppuration *ex vacus*, occurring as a result of retraction of the lung, does not disappear even after years, because the lungs do not apply themselves to the thoracic wall.

With the aid of the extensive material of the author's department of gunshot wounds, it may be shown for all these changes that they are the results of the insufficient respiratory activation of the diseased side of the chest, owing to the fact that in every case these (often very highly developed) changes could be made to disappear by suitable alteration of the respiratory movements.

At the same time it must be mentioned that in nearly all the cases seen by the author any additional surgical intervention could be avoided, even where several years had passed since the last operation, where the pyothorax cavity had definitely become "rigid walled," and the releasing of the lung could be easily accomplished with great deliberation and care.

The treatment of cardiac insufficiency constitutes the classical proof for the justified extension of the indication for respiratory therapy to the field of the respiratory organs. The stasis in the lower half of the body may be influenced etiologically, inasmuch as the strangulation of the ascending vena cava, which

the low position of the diaphragm produces, is relieved. The tendinous ramifications of the posterior crura of the diaphragm surround the quadrilateral foramen of the diaphragm, through which the ascending vena cava passes. Every increase of the muscular tone at this part of the diaphragmatic musculature produces a clamping off of the return blood stream in the ascending vena cava at the time of the sinking of the diaphragm.

The change in respiratory activity can act in a compensatory way in several directions. It may help the resorption of water and limit the work of the circulation, inasmuch as it combats the drying of the oral mucosa and the feeling of thirst by the elimination of mouth breathing which is so favored by dyspnea. It directly supports the return circulation by deepened aspirating inspiration, the pulmonary part by prolonged inspiration, and the abdominal organs by increased drawing inward of the abdominal musculature (active abdominal breathing) for the purpose of combating abdominal stasis as well as of expression of all the abdominal organs and also of the ascending vena cava. This example at the same time shows the differences between the formerly practised purely empirical respiratory gymnastics and the respiratory therapy developed on theoretical bases. The former was based upon the theory that respiration is a curative procedure, with an eye toward the greatest possible activity of respiration, without due regard for the form of the breathing produced thereby. The scientific analysis, on the other hand, showed that such a deepening of the respiration, carried out in the usual form, not only is not always useful, but may even be considered as the direct cause of severe injuries. In many cases the aim should be the direct opposite in a diminution of respiratory activity in general, or of one phase of respiration. Even where an increase in respiratory activity is desirable, as in atalectasis or induration formation, this increased activity must be confined to the changed portions, so as not to increase the compensatory emphysema and it must be undertaken according to very definite rules, so as to follow the principle of *primum nil nocere*.

On these grounds it appears in place now to give a short analysis of the useful and injurious effects of respiratory activity, and, first of all, to keep in mind the injurious effects:

The usually employed form of deep respiration, in which, chiefly and even exclusively, the inspiration is deepened and the expiration at least is not deepened just as much, and often even embarrassed in favor of the inspiration (air hunger), is distinctly injurious.

Just as injurious is the "holding of the breath" at the end of as deep as possible an inspiration, often advised by "breathing experts." The drawing of a breath with open mouth, often used for the easier accomplishment of the deepest possible respiratory activity, as well as the expiration through the open mouth, are similarly to be considered to be always injurious. By holding the breath, the return blood stream is kept back from the lower half of the body through the low position of the diaphragm. As a result of the inspiration through the mouth, the respiratory activity of the pulmonary apices is inhibited, thereby increasing a previously existing "predisposition" to tuberculosis, and also causing a drying of the mucosa of the respiratory passages as well as an injury of the ciliated epithelium of the same which have such a beneficent influence. From this can also be seen the usefulness of the opposite measures; the deepening of the expiration as well as the drawing of the breath through the nose. The former is of advantage because it diminishes the used air remaining in the thoracic cavity, so that sufficient renewal of the alveolar air is possible even with slight respiratory activity.

Suitably applied, the generally increased activity of inspiration (associated with increased expiratory activity) is more useful than the activity of the diseased part alone, and is therefore an apparently more specialized activity, even though the opposite holds good in general. An example of this may be seen in the combating of the asthenic habitus, the precursor of tuberculosis, enteroptosis, and other pathological conditions.

Heliotherapy in Advanced Pulmonary Tuberculosis.—I. D. Bronfin (*Colorado Medicine,* November, 1924) says that in his experience heliotherapy has not yielded encouraging results in this class of cases. Neither the favorable nor the unfavorable results can be attributed to it with certainty. It is as dangerous an agent as tuberculin if used injudiciously. There are many points of resemblance in the body reactions between radiation and tuberculin. Hemoptysis is no contraindication to its use. Extrapulmonary lesions are invariably favorably influenced by heliotherapy.

Peptone Therapy in Asthma and Other Anaphylactic Syndromes.—H. P. Miller (*Illinois Medial Journal,* April, 1924) concludes that peptone therapy in asthma and allied conditions offers a simple and effective mode of treatment. Physiological studies prove the identical nature of peptone and anaphylactic shock; peptone (proteose) treatment starts at the lower or less specific end of the reaction, while protein starts at the beginning of the chain or highly specialized end. Two tenths of one c. c. constitutes the initial dose given intravenously and repeated twice weekly. The dose is increased two or three tenths of a c. c. until about one and one-half c. c. is reached.

Therapeutic Uses of High Carbohydrate Diets.—T. Izod Bennett (*Lancet,* July 5, 1924) gives the following classification of the indications for high carbohydrate diets in adults and older children: 1, certain specific infections, such as, pneumococcal pneumonia, in typhoid and paratyphoid infections, and bacillus coli communis infections; 2, in certain infections of unknown origin, especially some cases of rheumatoid arthritis; 3, diseases of the heart and bloodvessels; 4, respiratory diseases, such as pneumonia and obscure cases of asthma; 5, diseases of the alimentary system, such as peptic ulcer, undernutrition and disorders of the liver; 6, diseases of the renal system. The most useful group of foods includes macaroni, vermicelli, noodles, and various substances prepared from flour, arrowroot, sago and other starchy substances. Many of the starchy vegetables, such as potatoes, carrots, and artichokes, are also useful.

Rheumatism in Infancy

ERIC PRITCHARD, M.A., M.D. (Oxon.)

London

The few remarks which I have to make on this subject are rather for the purpose of challenging criticism and asking for information from those who have greater knowledge of the subject than I have myself, than of throwing any new light on a matter which has been strangely neglected by pediatrists. From a perusal of the writings of most of our contemporary authorities on rheumatism we are led to believe that the periods of infancy and the early days of childhood are practically exempt from the symptoms of rheumatism. Rheumatism is either due to a specific infection or it is not. I believe that at the present time most authorities agree that the streptodiplococcus is an etiological factor of importance, but possibly not the sole factor; it is assumed by many that the specific organism of rheumatism, whether it be the diplococcus or some other filter passer, will not thrive and develop in the human tissues unless the concomitant circumstances are favorable for its growth. What these circumstances or what the required environmental or hereditary conditions may be will no doubt be thoroughly discussed by the many able contributors to this symposium[1] who, I understand, are dealing with the manifestations of rheumatism at other periods of life. For my part, however, I refuse to believe that, if rheumatism is due to the activities of some specific infective organism, the human body can be immune to its ravages at that very period of life, when its defensive mechanisms against practically all other forms of infection are notoriously defective. It is quite true that infants appear to be somewhat highly resistant to certain of the common exanthematous infections such as measles, scarlet fever, and chicken pox, but I would ask may not this apparent immunity be due either to the sheltered life which they usually lead, or to the fact that these diseases kill before they have had time or opportunity to develop the symptoms by which we are accustomed to recognize them.

I am convinced from a long experience of the institutional care of infants and young children that many casualties are due to epidemic influenza and common catarrhal infections without the true cause of the catastrophe being suspected. I have noticed time and again that, when in a general children's ward the nurses and older children have developed the typical symptoms of these conditions, the young infants have died like flies, without the manifestation of any of the usual evidences whereby the specific nature of their complaint could be recognized. Under such conditions marasmic and wasting infants often die suddenly from collapse without any obvious catarrhal symptoms or without any marked rise in temperature. Further, I have noticed the same inexplicable results follow when scarlet fever, diphtheria, and measles have been endemic in my wards. In explanation of these results I have suspected that the defensive mechanisms which in older children are called into play to arrest the development of the invading organism are ineffective or nonexistent in the case of the infant.

At different periods of life different mechanisms are called into play to protect the organism against the various dangers and disease provoking elements of the environment, and as one after another these various engines of defense are developed and the principles of the division of labor and cooperation are more strictly followed by the physiological processes of the human body, the individual becomes more resistant or immune to the common dangers of life. Striking examples in support of this general statement are to be found in the varying reactions of the human body at different periods of life, to food, thermal, psychological and mechanical injuries, it is perhaps unnecessary for me to give them in detail. But it is particularly in its reactions to the greatest of all the environmental dangers, namely the specific organisms of disease, that the body shows the greatest versatility and resource. The clinical pictures of tuberculous disease and syphilis are totally different in the infant and in the adult, and so are they in the case of practically all chronic infections.

Rheumatism is no exception in so far as we recognize its symptoms at different ages of life. In the young child it takes the form of tonsillitis and chorea, in the adolescent endocarditis and myocarditis, in the adult pleurisy, synovitis, arthritis, neuritis, and other conditions. In a general way one may say that the onus of defense in early childhood rests with the lymphatic system and the armies of leucocy-

[1]This refers to a symposium on rheumatism which will be published in the near future.

tes, in older individuals with the connective tissue cells, and possibly with endothelial cells, and the symptoms attributable to the calling into play of these special lines of defense explain the special character of the clinical picture.

My reason for making this contribution to this series of articles on rheumatism is to ask my medical confrères what are the particular mechanisms which are called into play in the case of the infant to defend it against the onslaughts of the rheumatic virus. Personally I believe they rest chiefly on the activities of the mucous membranes and the skin. I believe that we have just as much right to call a catarrhal enteritis or colitis, or a strophulus urticaria or eczema, rheumatic in the infant, as we have to call tonsillitis, or lymphatic adenitis, rheumatism in the young child. I have been in practice long enough to follow up cases of rheumatism from infancy to middle age, or at least to follow the life history of cases which have in early childhood developed into conditions which I was clinically justified in regarding and labelling as rheumatic, which in infancy have manifested symptoms of the nature stated, but which nobody would dare to call rheumatic.

Is it reasonable, or is it likely, that the infant who in most respects is almost defenseless in the face of most infections should have special immunity to the infection of rheumatism, or is it likely that the latter can be excluded entirely from his environment? Rheumatism is in most cases doubtless a slow chronic infection, but the evidences of its occasional occurrence in infancy can hardly be doubted, though the particular methods of defense may be quite different in infancy from what they are in later life.

Purulent Pericarditis in Childhood*

ALFRED C. WOOD, M.D.
and WILLIAM N. BRADLEY, M.D.
Philadelphia, Pa.

The relative frequency of purulent pericarditis in childhood, with the infrequency of its recognition and consequent high mortality, has prompted a brief consideration of the subject. Pericarditis is discovered most frequently at the autopsy table. For this reason it is impossible to determine its frequency with any degree of accuracy.

A recent study made at a Boston hospital covering a period of nineteen years showed that acute pericarditis occurred in four per cent. of all autopsies, and that pericarditis is much more common in childhood than in adult life. In 150 autopsies acute pericarditis was found to be present thirty-nine times, or 26 per cent.; seventeen of the thirty-nine cases were in patients under ten years of age. The ages in the purulent type were not mentioned. Pericarditis was diagnosed during life in only one hundred of 34,467 patients treated by able physicians in the wards of the hospital, while during the same period seventy-eight cases were found in 1,553 autopsies. (13)

Suppurative pericarditis in the first month of life occurs most frequently as a part of septic processes. In a series of sixty-six cases in patients under fourteen years of age reported by Baginsky, (19) twenty were purulent and eleven of these occurred in the first year of life. Other statistics (11) show that eighty per cent. occurs in children under four years of age and two-thirds of these are under three years. Still (21) reports twenty-three out of twenty-eight pus cases as occurring within the first three years of life.

ETIOLOGY

Suppurative pericarditis may occur as a direct extension by contiguity, or through the blood. In a great majority of the cases it is secondary to some other focus of infection.

*Read before the Section on Pediatrics of the Medical Society of the State of Pennsylvania, October 7, 1924.

Suppurative pericarditis in children most frequently follows in the wake of the acute infections, especially the exanthematous diseases, scarlet fever, measles, varicella and erysipelas. It may also result from inflammation of the neighboring organs (lungs, pleura, mediastinal glands, thymus gland, esophagus, intestinal canal and bones of the chest); likewise follicular angina, otitis and mastoid disease, osteomyelitis and bone caries, chronic nephritis, peritonitis, meningitis, abscesses of the skin and other pyogenic processes.

The cases which merit most attention are of pneumococcal origin. (11) It has been asserted that ninety per cent. of cases of purulent pericarditis are associated with empyema, pneumonia or pleurisy. In a study made at the Children's Hospital of Philadelphia only fifty per cent. of the cases were so complicated. (19) Brooks and Lippincott (29) found in their 150 cases of pericarditis, pleural lesions in 136. Robert's (5) series of thirty-nine cases revealed a history of some form of infection in either the lungs or the pleura in nineteen cases.

In the previously mentioned 1,553 autopsies (13) of the seventy-eight cases of pericarditis, acute pneumonia or pleuritis was found forty-nine times. Still (21) reports twenty-four cases out of twenty-eight as being associated with empyema or pleurisy.

In the 150 autopsies mentioned above, the thirty-nine cases of purulent pericarditis were complicated by pneumonia twenty times and empyema five times (13). Preble (28) in his series found pericarditis complicating pneumonia in thirty-four per cent.; rheumatism, 28.3 per cent.; chronic diffuse nephritis, 11.2 per cent.; tuberculosis, ten per cent.; sepsis, 4.7 per cent.; aneurysm, 2.6 per cent.; typhoid, 1.7 per cent. of the cases.

Preble (*loc. cit.*) analyzed a series of cases with particular reference to the degree of lung involvement due to pneumonia. When one lobe is involved

the chances of pericarditis are one to forty; two to three lobes, one to nineteen; four lobes, one to five; with pneumonia of the entire left lung, one to eight. He feels that the danger is somewhat greater with a leftsided than with a rightsided pneumonia.

One author has pointed out as a peculiarity of childhood, that pericarditis in the earliest periods of life depends chiefly upon pyemic infection; in middle childhood mainly upon the spread of inflammatory processes; and in later childhood generally upon rheumatic conditions. (24)

BACTERIOLOGY

While the bacteriology of suppurative pericarditis shows the occurrence of staphylococci, streptococci, Frankel's diplococcus, Bacillus pyocyaneus, Bacillus tuberculosis, Bacillus coli communis, Bacillus influenza, rarely Bacillus lactis aerogenes and Bacillus proteus vulgaris, (12) the pneumonococcus is preeminently the organism responsible for the condition in infants. The species of bacteria present, however, in a given case is that of the primary affection.

The pericardium may be infected at a very early stage of the primary disease, or as a terminal event. The effusion may be fibrinous, serous or purulent. A dry pericarditis of one day may be a pericarditis with effusion the next. The amount of fibrin in an exudate will vary greatly. Often there is only sufficient to coat the pericardium. At other times it is so abundant that the heart is covered with a plastic layer which may be as much as a centimetre in thickness. (7) It has been stated that the exudate in early life is usually purulent, in middle childhood serofibrinous, and later almost always purely fibrinous. (24) When pericarditis is due to the pneumococcus the pus is generally less abundant, thick and creamy; the two layers of the pericardium being completely covered with an envelope of thick, dark-yellowish fibrin. (1) When streptococcic, this liquid is, on the contrary, abundant, purulent, with the membrane only slightly thickened. (1) Large effusions are more apt to be serous. (1)

In pericarditis the myocardium is often attacked. (8) Indeed one of the earliest results of pericarditis is dilatation of the heart. As the visceral layer of the pericardium sends a fibrous meshwork carrying blood and lymph vessels into the myocardium, the inflammation is carried into the muscular wall. With every pericarditis, therefore, must be more or less myocarditis (22) and consequent cardiac weakness. Finally, it is not unusual to find inflammation of the mediastinum and pleura as well as bronchial and pulmonary complications.

SYMPTOMS

In the very young all the usual symptoms one expects to find may be absent. The temperature may be normal or subnormal. There may be no indications of the presence of cardiac disease or other abnormal physical signs. For these reasons some excuse may be made for failure to recognize the affection during life. (19) These facts emphasize the importance of a thorough physical examination at each visit, with complete notes and charts. Location lines may be left for comparison at the next visit. Aside from the fact that examination of the heart in the young is attended with many difficulties, there is scarcely another disease which presents as variable a picture as does pericarditis. (22)

The symptoms in a given case depend largely upon the pathology present. It is well to keep in mind these changes and the resultant physical findings. These (22) will include alterations in the surface of the pericardium, the presence of fluid exudate and changes in the condition of the heart muscle.

The history will usually reveal that the child has recently suffered from some acute infectious process, associated with fever, rapid pulse, dyspnea, restlessness, possibly cough and precordial, epigastric or abdominal pain. (20)

In cases with moderate effusion, palpitation, dyspnea and acceleration of the respiratory rhythm do not usually occur. (8) The pulse is usually rapid, but remains regular. (8) With increasing effusion, dyspnea, orthopnea, cyanosis, rapid, irregular and intermittent action of the heart develop. (22) In septic cases there may be in addition high fever and profuse sweating. (7) When effusion occurs the pain becomes less or may disappear entirely. (22)

DIAGNOSIS

As already intimated, the diagnosis in children is not the simple procedure one would ordinarily suppose. The reverse is a fact and there is no other grave malady so frequently discovered for the first time postmortem. (7) It is most important, therefore, to remember this fact and not make the mistake of attributing any suggestive symptoms to the already known conditions. (13, 4, 7, 1)

While in most cases acute pericarditis is a rapid process, in some cases the onset is insidious. Occasionally cases occur which run a mild course in the beginning, grave symptoms develop suddenly with dangerous complications. (22)

The apex beat in exudative pericarditis of children, may move to various points within the area of dullness, by change of the child's condition, if the heart has not lost its motility in the pericardial sac. (24) When the child bends forward or is placed in the knee chest position, the apex beat which previously may have been absent may reappear. (22, 24) With small effusions there is little change in the force or position of the cardiac impulse or in the intensity of the heart sounds. In larger effusions the apex beat may be higher up and farther to the right, even in the fourth space near the sternum, the explanation being that the effusion allows only the front of the ventricle to strike the chest wall. The impulse may disappear to inspection, but still be palpable. (23) In extensive effusion the impulse is usually neither visible nor palpable, the heart sounds being very feeble or completely absent except at the base. Diminution in the intensity of the heart sound is not accompanied by a corresponding weakening of the radial pulse—an important point in diagnosis. (23)

Obliteration of the intercostal spaces and even bulging of the precordia, with immobility, may result when effusion develops in sufficient amount. (23) In these cases there will be an increase in the area of cardiac dullness, an enfeebled or lost apex beat and auscultatory sounds. The pulse rate is considerably accelerated, sometimes reaching 150-180 to

the minute, in small children. (24) In most cases of large pericardial effusion one finds some modification of the voice and breath sounds, either intensification or diminution, below and internal to the angle of the scapula. (13)

FRICTION

Friction rubs may be constant, intermittent or absent. One writer (27) believes that they are present in every case some time in its course, and that systematic examination will reveal them. Others believe that they are exceptional (33) and that pericarditis can develop and go on to effusion without the characteristic friction rub being detected except by the closest and most frequently repeated observation. The friction murmur varies in character, depending upon the age and physical character of the exudate. (24) The friction, when present, may be evident to both palpation and auscultation. (20)

If present it is usually loudest at the base of the heart, and changes in intensity with change in position or pressure with the stethoscope. (3, 24) It becomes louder when the child sits up, walks or bends forward, or when pressure is made with the stethoscope, and more feeble when the child lies on its back. (24) As the pericardial surfaces are kept separated with larger effusions, the friction usually disappears, and a decided increase in the area of dullness is observed. (24) A friction murmur, when present, accompanies one phase of the cardiac cycle. It may be systolic or diastolic or have a three beat rhythm—due in part to change of position of the patient. In infants and young children the recognition of the friction rub is difficult and often impossible, on account of the rapid action of the heart, (23) and it may be mistaken for a valve murmur. The rub may move from day to day, and disappears with resolution or the formation of fluid. The effusion may be so extensive that it fills the entire left chest, pushing up the lung and giving the same signs as pleural effusion. (23)

The disposition of the effusion with relation to the heart itself is of importance. The conception that the fluid in pericarditis is evenly distributed about the heart is certainly not correct. The fluid tends to accumulate in the lowermost part of the sac. With the patient in the supine position, the fluid would accumulate in the posterior part, and the anterior surface be but scantily covered. If it is possible to put the patient in the knee chest position, an increasing cardiac dullness can be noted. (7) A recent study by Williamson (15) shows that fluid first accumulates along the lower margin of the heart about the apex, and next over the great vessels at the base. The result in the first instance is to push the left lobe of the liver downward, and the second result is a retrosternal dullness—both of which constitute important signs. Studies were made by Rotch, (37) as a result of which he concluded that the obliteration of the cardiohepatic angle was a conclusive sign of pericardial effusion. While this sign is still quoted, it is our impression that it lacks the importance attributed to it by Rotch.

In respect to diagnostic symptoms in the presence of effusions, one general statement may be made, viz., the more rapid the development of the effusion, the more severe are the symptoms likely to be. In other words, a large effusion which has taken some little time to form, so that the heart and lungs have had time to adjust themselves, may be attended with much less distress than a much smaller effusion which has formed rapidly and has not given so much time for compensation. (1)

The cardinal diagnostic points which are usually set down are: (30) 1, Increase in the cardiohepatic angle; 2, increasing faintness of the cardiac sounds; 3, disappearance of cardiac impulse; 4, pulsus paradoxus. The latter may occur in other conditions and even in normal subjects. (3)

In determining increase in the area of cardiac dullness, it is important to remember that the apex beat is, as a rule, outside the mammary line until the fourth year; from the fourth to the ninth year in or near the mammary line; after the thirteenth year, under normal conditions, it is invariably within the line. (20) Normally cardiac dullness extends from one quarter inch beyond the right margin of the sternum, to the left vertical nipple line, and in very young children one quarter inch beyond. (20)

In moderate effusions there is slight absolute dullness in the fourth right interspace, more marked absolute dullness in the fifth interspace, an obtuse cardiohepatic angle, and enlargement of the precordial dullness to the left. (23) This area of dullness is usually triangular, with the base below, (23) and has been described as a bag filled with water set down on a table. (3) The larger the effusion, the farther does the area of precordial dullness extend, both to the right and to the left. (23) In very large effusions the area of dullness is rather circular, the cardiohepatic angle again becoming acute. (3) A progressive increase in cardiac dullness constitutes the most reliable evidence of a pericardial effusion. (7) Daily noting this broadening area of dullness, one will appreciate more forcibly the dullness in the cardiohepatic angle; and the fact that while the cardiac dullness is increased in all directions, the greatest increase is along the base line. (23) As a collateral sign of pericardial effusion, Pins of Vienna long ago pointed out evidences of pressure exerted upon the lower left lobe of the lung. (7) Almost all authors (Billings (27), Babcock (30), Cabot (32), Parkinson (35)), call attention to this small area of dullness in the left back, just inside the angle of the scapula, as described by Ewart, and produced by the mechanical atelectasis of the compressed lung. (3) Ewart (25) describes this patch of marked dullness present in pericardial effusion, as extending from the spine outward not quite so far as the scapular angle line and ceasing with its vertical outward boundary extending upward to the ninth or tenth rib and for a short distance to the right of the spinal vertebræ. Rarely, however, is this sign determined with the exactness laid down by Ewart's boundaries, (7) and as a partial consolidation of the lung or of a pleural effusion, as well as compression of the lung by the distended pericardium, may account for them. (7) Ewart's explanation (26) is interesting but not conclusive.

DIFFERENTIAL DIAGNOSIS

It may be well to point out a few of the difficulties which confront us in the individual case. Considering the intimate contact of the pericardium with

almost all the structures of the thorax, it is not remarkable that pericarditis may be mistaken for other affections of the thoracic or abdominal viscera. (3)

ENLARGED HEART

The enlarged heart will give an increase in the area of dullness both to the right and to the left. The left limit of precordial dullness corresponds to the apex beat or extends a little beyond, while in pericardial effusion the dullness usually extends notably beyond the apex beat. (23) Also in enlarged heart the cardiohepatic angle is acute, while in small and moderate effusions in the pericardium, it may be obtuse. (23) The area of dullness and bronchial breathing referred to as occurring in the back on the left side is almost never caused by enlarged heart alone. (23) As regards cardiac hypertrophy, this may be surmised with fair accurateness by inspection and palpation, suggestive signs being: a large area of pulsation and possible precordial bulging, increased dullness to the right with a diastolic thrust in the epigastrium, pointing to rightsided hypertrophy, and a large area of cardiac dullness to the left; a systolic thrust of the apex well outside the nipple line, suggesting left ventricular hypertrophy. (20)

Dilatation of the heart may give rise to enlargement similar to that of effusion, but this being enlargement of either right or left ventricle, has not the symmetrical enlargement of pericardial effusion. (7) A cardiac dilatation may be sudden, progressive and extreme, especially that of the right side of the heart. The dullness may extend from the right nipple to two or three inches outside the left nipple line, thus simulating pericardial effusion, and to be differentiated with difficulty.

DULLNESS

Both Gibson's notch and Rotch's notch acquired their chief importance from the result of experimental injections into the pericardium. These are now believed to be of little practical value. (1) As regards cardiac dullness in the presence of effusion, three particular signs have been pointed out, all of which have been questioned by various authors. The first of these is described as an increase in cardiac dullness, outwards and upwards on the left side along the third space or rib. (1) This leads to the disappearance of the cardiomediastinal notch described by Gibson and named after after him—Gibson's notch. This condition is often seen in pericarditis without effusion, or other forms of heart disease, where no pericarditis exists at all, possibly being due to a dilatation of the left auricle. (1) Rotch (*loc. cit.*) called attention to increasing dullness in the fifth and sixth interspaces on the right, with increasing effusion. This results in a disappearance of the cardiohepatic notch on the right side known as Rotch's notch or angle, and was formerly regarded as an early sign of effusion. (23) Williamson (23) was unable to demonstrate Rotch's sign or that the position of the patient influenced the character of the cardiac dullness. (1) The third sign, that of Ewart, has already been described.

It is from dilatation of the heart particularly that pericardial effusion must be distinguished (10). With dilatation the impulse can usually be made out as far as the dullness extends at the apex (1). While the epigastrium may be prominent in both cases, in pericardial effusion there is often epigastric recession; in dilatation there is mostly systolic protrusion (1).

Pleuritic effusion.—A large pericardial effusion in which the precordial dullness on the left merges with the dullness in the left back, may be mistaken for pleurisy (23). Pleurisy of the left base is common in pericarditis (20). When pericardial effusion occurs in association with pleuritic effusion, as often happens in empyema, the recognition of the former is still more difficult, unless a typical pericardial friction rub be present (23). Likewise a massive pericardial effusion considerably compressing the left lung might be mistaken for a pleural effusion if sufficient stress were not laid upon the position of the apex beat of the heart, which is shoved to the right side with pleurisy and is absent with pericarditis (24).

Empyema.—In the presence of most cases of empyema, purulent pericarditis is not diagnosed, either because the symptoms are masked or because there are no definite cardiac symptoms at all (1). In others, a diagnosis of leftsided empyema may be made, and on opening the side, after finding or not finding pus in the pleura, the pericardial sac may be felt bulging, and incision through the pleural opening shows it to contain pus (1). The important points in pericardial effusion are absolute dullness in the fifth right interspace with an obtuse cardiohepatic angle when the empyema is on the left; extension of the dullness to the left, notably beyond the apex beat, when the empyema is on the right side; and weak impulse with faint heart sounds. Of course, a typical pericardial friction rub is the greatest aid in the recognition of these cases, but this is often absent and pericardial effusion complicating empyema is frequently overlooked (23).

Likewise a leftsided empyema may produce cardiac dullness to the right and obscure the limits of cardiac dullness to the left (7). In a similar manner a pleural effusion on the right, a pneumonia, an enlarged liver, abdominal distention, displacing the liver and diaphragm upwards, or still more commonly the noisy respiration or restlessness of an extremely sick child, may make observation difficult or misleading (7). It may be distinguished from an enlarged liver by the faintness of the heart sounds and the disappearance of the cardiac impulse (3).

Loss of abdominal respiratory movement has already been mentioned as an accompaniment of pericarditis, often preceding and surviving the friction sound (16). Wynter (*loc. cit.*) reports a case in which remarkable stillness of the abdomen led to a diagnosis of an acute abdominal condition, which later proved to be pericarditis. Purulent pericarditis, particularly following measles, whooping cough and influenza, frequently passes unobserved, except when friction occurs, or in the presence of a large effusion (11).

Gibson (23) found pain in seventy per cent. of cases; Sears in sixty-five out of one hundred cases (3). Babcock (30) found pain in a majority of his cases, and if pain was absent there was a sense of distress. In Robey's (3) series of seventy-eight

cases, pain was present twenty-six times. Of these twenty-six patients, seventeen had either pneumonia or pleurisy and only six had pain directly over the precordia. In two purulent cases operated upon, pain was never present (3). While opinions differ, the most generally accepted is that the majority of cases do not have much pain (2, 3).

X ray evidence.—Williams in experimental studies reported in 1903, states that the signs in pericardial effusion differ with the amount of fluid present. The larger amount increases the shadow of the cardiac area and the heart shadow becomes more rounded. In small effusions, it should be remembered that the fluid is largely in the most dependent part of the pericardial sac.

Holmes (14) states that the shadow of the dilated heart resembles very closely that of pericarditis with effusion. The heart shadow is rounded and there is no change in position of the patient.

Comparing röntgenograms of pericardial effusion with those of dilated hearts, the line in the latter is almost always a curve inward as it nears the liver.

The x ray findings in pericarditis with effusion may be summed up as follows (36):

1. Heart globular in shape and enlarged symmetrically, with widened base.
2. Heart shadow larger in the recumbent posture than in the vertical posture.
3. Diminished impulse of the heart under fluoroscopic examinations. This is due to sac fluid.
4. The obliteration of the costocardiac angle, due to fluid in the pericardial sac, is unreliable, as conditions of the pleura and lungs involving that region simulate distention and enlargement of the heart.

Finally we believe the x ray to be a valuable aid in the diagnosis of pericarditis in children; only, however, when studied in connection with the physical findings. It aids in pointing out complications.

PROGNOSIS

Purulent pericarditis in children, whether due to the pneumonococcus, streptococcus, or some other organism, is usually fatal (11). It is practically always a fatal complication in infants (23). In many cases of latent purulent pericarditis, death is sudden. This is due to cardiac syncope, the result of the myocardial changes which are more extreme with purulent than with other forms of pericarditis. The pneumococcic type is one of the causes of sudden death in pneumonia (1). The quantity of exudate has a definite relation to the prognosis (7). Studies indicate that whatever the nature of the pericardial effusion, if it be accompanied by low blood pressure and weak, irregular heart action, the pressure within the pericardial sac should be lowered by aspiration or drainage (4).

TREATMENT

The only form of treatment holding out any hope for cure in purulent pericarditis is surgical incision and drainage. In Elliott's table (4) of twenty-two cases of suppurative pericarditis treated by operation in seven of which the patients were under sixteen years of age, only one recovered. The prospect of a cure after operation is much more favorable where the infection is limited to the pericardial sac than where the pericarditis is part of a general sepsis (4). That occasional recoveries are secured in this latter group, however, warrants surgical interference where the patient is not moribund (4).

(*To be concluded*)

Atypical Influenza in Children

MICHAEL SCHUMAN, M.D.
New York

The subject of atypical influenza in children is particularly timely for the reason that, although unaccompanied by the usual newspaper publicity, there has been a definite epidemic of influenza among children during the past three months. As a matter of fact, since the last great pandemic of epidemic influenza in the United States in 1918, there have undoubtedly been recurrences during the last few years, occurring especially from December to March.

The various epidemics have, however, been characterized by certain peculiarities with regard to type and localization as well as to virulence. For instance, during 1921, a great majority of the cases showed ear infections of marked severity with considerable mastoid involvement. Purulent otitis media was common; mastoid operations were frequent. In last year's series there were many cases of otitis media, mastoiditis was comparatively rare, and respiratory complications were markedly in evidence.

I am basing this discussion of atypical influenza in children or, as it may be termed, the present epidemic of influenza among children, upon a study of about three hundred cases seen in private and consultation practice during the last three months. But before proceeding with this discussion, let me summarize briefly, the various types of influenza which we have encountered during the last two years, types which are fairly definite in their clinical and physical syndromes and types which unless considered as such are often mistaken for, and classed as, definite clinical entities depending upon the predominant complications present.

We may recognize at least six distinct types of influenza, as follows:

1. The type usually referred to as the grippe, more specifically the nasopharyngeal type, with coryza, a thin mucous nasal discharge, sneezing, conjunctivitis, and a red congested throat involving the tonsils and the pharynx. The temperature varies between 100° and 104°. There is a poor appetite which occurs early in the onset and continues throughout the course of the disease. After a comparatively short period there appear an extreme loss of weight and strength entirely out of propor-

tion to the apparent illness. The chest and abdomen are negative. It is this type which is particularly prone to several relapses before complete recovery takes place.

2. This type is marked by congestion of the upper respiratory tract and especially by a tracheitis, showing in addition to the above named symptoms a progressive hoarseness and a dry paroxysmal cough simulating whooping cough. This last condition is particularly intractable to treatment and constitutes an especially disturbing factor, delaying the ultimate recovery of the child.

3. In this type the symptoms start with a coryza involving the throat and mucous membranes as described above, but within a short time, a bronchitis involving the smaller tubules of the lung occurs, with a bronchopneumonia developing shortly thereafter. The peculiar edematous throat persists for some time after the pulmonary involvement has subsided and the cough remains dry and irritating. The course of the disease is apt to be rather protracted, with signs of physical exhaustion and toxemia on the part of the patient.

4. The intestinal symptoms are predominant in this type. Beginning as in the first class, severe constipation with cramps and distention, or diarrhea with watery mucous stools containing undigested food and often streaked with blood, soon occurs.

5. This is the nervous type which is the most serious form, but fortunately occurs least frequently. It may involve either the brain or the general nervous system or both. It is marked by extreme irritability, headaches, pains in the muscles and limbs, convulsions, stupor, coma and retraction of the head, and is apt to run a course of high temperature with rapid pulse. Of all the types, this is the one most likely to end fatally.

6. There may be combinations of two or more of the aforementioned types.

During the present epidemic, I have been much impressed with certain clinical observations that have occurred over and over again. The child runs a temperature for a day or two, has a running nose, with a thin mucoid discharge, loses its appetite and, on examination, shows merely a red throat, with or without congested ear drums, although the landmarks of the drum are easily made out and the light reflex is present. A day or two later, with a persistence of the red throat and the otitis, a cough develops. The temperature is generally fluctuating, perhaps between 100° and 104°. It has been my experience that the otitis, if one compares the incidence of purulent otitis and mastoiditis in previous epidemics, does not often develop into the purulent type. Bronchopneumonias, contrary to our experiences of last year, have been comparatively few as a result of a grippe infection. In some cases there is pulmonary congestion with localized dullness on percussion, but the picture of a definite bronchopneumonia, both clinically and on physical examination, is not present. Moreover, these symptoms are often both migratory and transitory, spreading from place to place in the chest and lasting for perhaps two or three days. In some cases they are, however, quite protracted, although the general effect upon the patient is not as severe as one might be led to expect. In a good many children, the urine examination shows traces of kidney irritation, such as the presence of albumin and an occasional cast or pus cell. Acetone is generally present, and the urine presents a high specific gravity with a strongly acid reaction. The blood examination generally shows a moderate increase in leucocytes. Throat cultures taken on the ordinary broth or agar medium, although showing the presence of many organisms, rarely exhibit a growth of the influenza bacillus. These are found chiefly in the lower respiratory tract, less often in the nasopharynx, and rarely in the ear discharges. They can, however, be demonstrated by obtaining a specimen of the mucopurulent discharge raised by the child when gagging or coughing, and when immediately grown upon a blood agar plate, for the influenza bacillus belongs to the hemoglobinophilic group. There generally are found in these cultures contaminating strains of streptococci either of the hemolyticus or viridans type, the staphylococcus and the pneumococcus.

Some children show a cervical adenitis and although accompanied by an elevation of temperature, fluctuating in nature, we cannot but be impressed with the fact that here again, few cases advance to suppuration which necessitates opening the abscess.

Some patients show the presence of a rash or a scarlatinaform erythema accompanying this condition, which is often mistaken for scarlet fever, especially in view of the ever present coryza and the red grippal throat. However, this rash is characterized by a rather abrupt appearance and by a certain transience, as it disappears within twenty-four hours or lasts possibly two or three days at the most. It is red, of irregular distribution, rather macular in character, without elevation to the touch, appearing particularly on the front of the body, less often on the extremities, and leaves no residual staining on disappearance. These patients do not desquamate as a rule and certainly not upon the palms of the hands nor the soles of the feet, as in scarlet fever. And where there is desquamation, it has been of the fine branlike type. The differential diagnosis depends upon a careful consideration of the mode of onset, upon the symptoms in general, and upon the character of the eruption itself.

We have seen some children who show symptoms of an acute cholangitis with marked jaundice and considerable tenderness over the liver. This complication is most apt to occur in the gastrointestinal type.

In children who have large tonsils and adenoids one often sees an attack of influenza running a rather protracted temperature course, with one or both ear drums congested, which do not go on to suppuration. There apparently are no other localizations or complications present. Upon careful examination, one will often find a sinus involvement, which is apt to be overlooked, unless this complication is considered as a possible explanation of a long drawn out illness and particularly of the continued high temperature.

In infants, the course of influenza is likely to be mild, even though they have no individual immunity to the disease. For that reason, it is not necessary to stop nursing breastfed babies should

the mother have a mild type of influenza. However, this precaution should be taken when the disease assumes a serious aspect.

An attack of influenza, per se, confers very little or no immunity, hence recurrences or frequent relapses are quite common. In fact, one often meets with a type where the temperature reaches normal within a few days after the onset, only to rise again and to assume a fluctuating character within twenty-four hours, with evidences of characteristics similar to the first attack. This may repeat itself several times before the ultimate subsidence of the disease. A characteristic of the type met with during this epidemic is the generally low virulence, and while one occasionally sees a case of severe virulence, it would seem that the contaminating strain of streptococcus, staphylococcus, or pneumococcus is responsible for this increased virulence. It is also true that the influenza bacillus itself is likely to gain in virulence by successive passage through various hosts.

TREATMENT

Heretofore, it was the usual custom to prescribe antipyretics as a routine procedure in influenza. In fact, aspirin and phenacetin and salol were considered almost specific. In the present epidemic, I have entirely discarded the use of these drugs. They have had little or no effect in my hands upon the course of the disease and neither have they affected the possibility or probability of the complications mentioned above. Acting as antipyretics they would reduce the temperature and perhaps thereby make the child more comfortable, but when one considers that the temperature is fluctuating, that the high temperature is generally of short duration, and that the effect of antipyretics in general is not a wholesome one upon infants or children, my reasons for discarding them should be apparent. The drop in temperature, the reason for which is rarely understood by the parents, gives the mother a false sense of security and nullifies, in a measure, all our efforts at control of the child to prevent the possible development of untoward complications. And of what value is the temporary reduction in temperature? For upon withdrawal of the medication, the temperature promptly rises, only to continue as before. Children bear temperature changes very well, and a sponge bath with alcohol, or a tepid bath, seems to be sufficient to control the effect of high temperature. Rarely, if ever, in influenza does a cold pack have to be resorted to. The patient should be kept in bed during the entire time of the illness, and for at least forty-eight hours after the temperature has entirely subsided without any fluctuations or evening rise. This will tend toward complete recovery and lessens the probability of a relapse.

Fresh air and a liberal amount of water should be allowed. Laxatives should be used when indicated. I prefer milk of magnesia administered either plain or in the milk feedings, because of its alkalinity and because its action is comparatively mild and without the griping effect of other cathartics.

The complications should be treated as they arise. I have previously mentioned the frequent occurrence of acidosis as an accompaniment of this disease, and have found nothing better than the early administration of alkaline treatment using the potassium citrate or acetate and bicarbonate of soda in doses of ten to thirty grains three times a day. In children showing gastric or intestinal symptoms, where the distention is marked, great relief is experienced from the daily use of high colonic irrigations with bicarbonate of soda, one dram to the glass using two to four glasses or even more at a time. I am inclined to advise this as a routine measure beginning early in the disease.

COMPLICATIONS

In discussing the complications during this epidemic, it has already been stated that the necessity for operative intervention for purulent otitis media is comparatively infrequent, and I must strongly condemn the unscrupulous attitude of some otologists who, for reasons best known to themselves, frequently do a paracentesis without taking this fact into proper consideration. The few in which operative measures are necessary subside soon after incising the drum and mastoiditis as a complication has been met with rather infrequently. I might call attention here to the fact that in children running high temperature with accompanying otitis, possibly purulent, the incision of the drum and the establishment of proper drainage is often not followed by a drop in temperature as one might expect. The temperature continues to fluctuate because, as a matter of fact, the otitis media is merely an incident in the general infection and it is the latter which governs the continuation of the general clinical picture. During this epidemic I have used as a routine measure early in the disease, a solution of adrenalin chloride, one to one thousand, one dram to the ounce of distilled water, using five drops three times a day in each nostril, in the belief that the reddened ear drums are due to a congestion of the Eustachian tubes which are rendered patent by the use of the adrenalin. In cases where this solution has been used, the otitis has, in my experience, been very mild in character and rarely, if ever, has it been followed by a purulent condition. One should not use this solution too frequently and as a further precaution should discontinue its use after five days, to resume it again, if necessary, two days later.

In children with enlarged tonsils and adenoids, the course, particularly as to temperature, is often a protracted one. Severe frontal headaches often accompany it, with a thick mucoid nasal discharge and with swollen tonsils much congested, but rarely of a follicular type. Here one should be on the lookout for sinusitis, and if found, the use of a suction apparatus applied to the nostrils will often result in a gradual drop in temperature and a lessening of the nasal discharge, and will hasten the ultimate recovery.

One of the most distressing complications which we have met with during this epidemic is a peculiar paroxysmal cough occurring with the tracheitis and pharyngitis. This cough is at times so spasmodic and explosive as to suggest the possibility of whooping cough or the presence of a foreign body. The cough is persistent and resistant to all forms of treatment. Sedative expectorants, medicated

vapor inhalations and antispasmodics are of no avail. Codeine may have to be resorted to in liberal doses. Cocaine solutions of one half of one per cent. have been used, applied locally to the retropharynx. A change of air to a warmer climate may act as an ultimate cure. In some of these cases, there is seen a severe edema affecting the entire pharynx and particularly the uvula which becomes swollen and elongated, so much so as to act as a foreign body. I offer this as a possible explanation for some of these intractable persistent coughs.

DIET

Contrary to the old method of reduced diet in all febrile conditions in children, we are leaning toward the belief that feeding these children liberally, using plenty of cereals, vegetables, milk and fruit juices, with plenty of water, increases the vitality and resistance and lessens the tendency to further complications. Particularly is this true where acidosis is present and where vomiting is frequently a disturbing factor. These children will often retain thick cereal gruels where they would be likely to vomit liquids in general. This in combination with the colonic irrigations and the alkaline treatment should afford early relief. We have not yet reached the point where we are to include proteids such as meats, eggs, or even Jello, in the diet.

CONCLUSION

In conclusion, I might add that children with influenza should be isolated, and as a further precautionary measure no operations, even of a trivial nature, should be undertaken during this period if they can possibly be delayed for a more opportune time. Furthermore, the mortality reports for this epidemic are very low, and recovery is the rule, for the disease is, to a great extent, self limited.

Röntgen Studies and Treatment of Enlarged Thymus in Children*

C. WINFIELD PERKINS, M.D.
New York City

The thymus gland in children presents an interesting subject for clinical and x ray exploration; for its enlargement may be accompanied by dangerous symptoms. The fact that children may have an enlarged thymus which is not accompanied by its characteristic symptoms of stridor, cyanosis, asthma and respiratory difficulties, is fraught with grave consequences, especially when operative proceedings are contemplated; for such patients are prone to sudden death under an anesthetic. "It is well proved by a long series of cases, carefully studied, by competent observers that the condition known as status lymphaticus is an entity, which is characterized clinically by a lowered vitality or unstable equilibrium of vital forces, so that accidents or disturbances otherwise unimportant, such as some slight injury or a light anesthesia may precipitate a failure of the heart or respiration. That T and A subjects are prone to enlarged general lymphatic structures, such as the thymus, is well known, especially at an age when it should have disappeared. Many of the sudden deaths due to chloroform and ether have proved to be due to an enlarged thymus (1).

Many children with enlarged tonsils are now operated upon and every now and then we hear of a sudden death without apparent cause, but when a postmortem examination has been made, an enlarged thymus is revealed. This condition is especially grave for the reason that these little patients have not presented previous clinical symptoms of a hypertrophied gland. That the life of an apparently normal child can be suddenly snuffed out without known cause is certainly alarming and of grave professional consequences.

Gwathmey (2) in his recent book states: "In extremely rare and unusual cases of status lymphaticus, the organs may be diseased and anomalous, it is quite conceivable that the heart may be paralyzed before respiration ceases. When paralysis occurs, from the condition it is usually in primary anesthesia. Until recently it has been the custom to give chloroform to children and a number of deaths have been reported of children dying two to three days after its administration and postmortem revealed that the children had what is known as status lymphaticus.

The clinical evidences of this condition do not warrant its certain detection beforehand, but the anesthetist will be wise to be particularly on his guard when the patient is a child or a young adult of slight physique, pale complexion or with large tonsils and adenoids. A majority of writers agree that a positive diagnosis during life is difficult. Cocks considers an x ray examination second only to the general condition of the patient in making a diagnosis. Halstead points out the great danger of operation for adenoid and tonsils upon children with status lymphaticus, on account of the great shock with fright and violent struggles, which in some cases produce death.

The association of sudden death with thymic enlargement is not new, for 250 years ago the investigations of Morgagni proved it was possible. Lee in 1842 and Howland in 1907 refer to sudden death due to laryngeal spasm and asthma in children.

Congenital enlargement of the heart with its attending clinical symptoms of stridor and cyanosis has been at times confused with thymic enlargement, and it is only by x ray exploration of the chest that a differential diagnosis can be made between the two diseases.

The x ray investigation of the chest in infants and children presents many differences, such as enlarged mediastinal shadow, small area of the lungs, and

narrowness of the ribs. The technical difficulties are many, the most important of which is the inability of having cooperation of the patient. It is necessary to make the exposures as soon as possible—when you can get them—on either respiratory impulse. A plate taken at six feet (teleoröntgenographic) is

Fig. 1, B.—Hypertrophied thymus gland in an infant aged eight months; arrows point to enlarged gland.

always advantageous in procuring a less distorted view of the anatomy. It is expert work to get good diagnostic chest röntgenographs of infants and children and it often requires great patience, tact and quick work on the part of the technician, a feature of röntgenology which is not often appreciated by the physician not doing x ray work.

In newborn infants and young children with cya-

Fig. 3, B.—Enlarged thymus in a child aged three years. Note difference in the base of the heart, and continuous shadow upwards.

nosis and respiratory difficulties, an enlarged or persistent thymus should always be considered. The röntgen examination of the chest may not only show an enlarged thymus, but it will likewise give clue to the pathology in the heart or lungs. The diagnosis of thymic enlargement is not free from possible

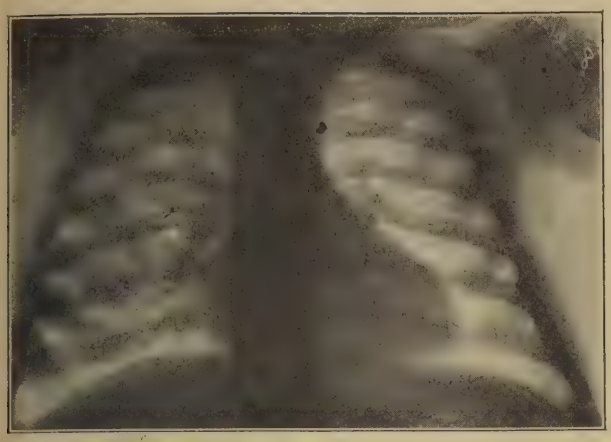

Fig. 4.—Patient had a low placed enlarged thymus which did not show in the x ray examination. This patient was operated upon and died in the primary stage of anesthesia.

error, for the enlarged gland may be placed so low over the heart that the two organs are apparently fused and the x ray will not demonstrate a mediastinal smooth bulging silhouette at the base of the heart characteristic of an enlarged gland. The film may show also a large shadow at the base of the heart during expiration but not on inspiration.

In recent investigations E. T. Evans, (3) Boston, states that the persistence of the thymus gland as a relatively normal condition has been demonstrated, although a positive x ray is not always in evidence, but secession of the symptoms are frequently noted after x ray treatment. Many sudden deaths of children formerly supposed to be due to bronchopneumonia, congenital anomaly of the heart or acute intestinal indigestion, in which autopsies have given little information of the cause of death, may have been due to unrecognized thymic hypertrophy. Such types of cases have recently been examined, considering the possibility of thymic enlargement in spite of a possible negative x ray, treated as such, with the röntgen ray with accompanying happy results and the disappearance of the cyanosis and dyspnea. The presence of an enlarged thymus in older children as compared with the newborn and infants is not as dominant, however, a sufficient number of older children do possess this pathological state, that a rigid clinical and x ray examination should be made before operative procedure, a possible collapse and a sudden death may by this means be forestalled.

Fig. 5.—Shows anterior and posterior view of the postmortem findings of the patient shown in Fig. 6. A very large thymus, which weighed thirty-nine grams, was situated so low over the cardiac shadows it was impossible to see in the röntgenograph.

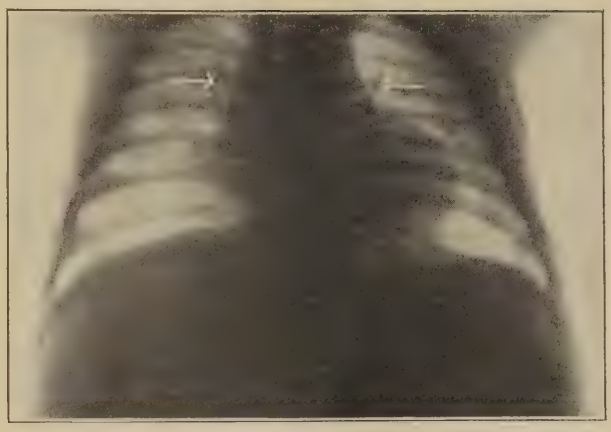

Fig. 6, A.—Enlarged thymus in an infant six months old.

Recently in a series of 237 T and A patients at the Seaside Hospital, ten definite cases of thymic enlargement were found and eight cases with a suspicious broadening of the base of the heart were observed. The patients' ages ranged from a few months to twelve years. In the positive cases the patients were not operated upon and those who remained in the hospital were treated by x ray for the enlargement. One patient died suddenly under primary anesthesia, who röntgenographically and clinically did not show an enlarged thymic shadow. The subsequent postmortem examination proved that the hypertrophied thymus was lying low over the heart, therefore in the x ray the silhouette could not be visualized by the examination, because the two shadows were fused. The thymus in this patient weighed thirty-nine gm. This thymus in the x ray did not show, however, the exception in this case does not prove the rule.

Many broad chested children under three years

Fig. 6, B.—Shows reduction of the gland after one x ray treatment.

of age as a rule show a wider base of the heart. This broad base should not be confused with thymic hypertrophy, unless other clinical signs should warrant a diagnosis. In over 500 cardiac examinations of children and infants at the Seaside Hospital, we

have observed the above normal appearance. The x ray examination of the chest may differentiate between a negative and positive thymus, depending to the extent of the bulging shadow at the base of the heart, either to the right or left of the median line.

It is not our experience with many hundreds of chest and cardiac examinations during the past three years, that an enlarged thymus exists as often as asserted by some authorities. In a series of 237 T and A cases, children of all ages, a positive thymus was found in ten patients. The treatment of thymus enlargement was formerly by surgery, but the mortality was so high that the surgical treatment has been superseded by x ray treatment, which is safe and satisfactory in the majority of patients.

This paper has been largely the result of ideas entertained as the result of the unfortunate outcome of treatment in the patient, whose history I shall now describe:

CASE.—R. H., four years, admitted at the Seaside Hospital Orthopedic Service on August 5, 1924. Physical examination revealed pale, poorly nourished child with rachitis. Patient was built up and gained two pounds in the hospital. The x ray examination of the thymic region was negative. Three weeks later the patient was prepared for operation, to correct the knock knees and anterior bowing of the tibia. While under primary anesthesia, the patient suddenly ceased breathing without warning, and all efforts to resuscitate the patient were unavailing.

Postmortem findings: The gland was enormously enlarged, weighing thirty-nine gm. It extended downwards two thirds over the pericardium. A general hyperplasia of the glands of the mesentery was also noted. The enlarged gland was so low over the pericardium, that the shadow could not be differentiated from the heart in the x ray examination.

SUMMARY

1. All children before operative procedure should be studied both clinically and by means of x ray for enlarged thymus.

2. Sudden death without previous clinical symptoms may result as the result of primary anesthesia or mild shock to the system.

3. Congenital anomaly of the heart and thymic hypertrophy can be differentiated by röntgen examination, although the symptoms may simulate one another.

4. All children under three years present a broad base of the heart, which should not be confused with an enlarged thymus.

5. An enlarged thymus gland may be placed so low over the pericardium, that it will not cast a characteristic shadow, when examined by means of the röntgen ray.

6. The x ray presents a satisfactory method of treatment of enlarged thymus gland.

Meningococcal Meningitis in Young Children

*Practical Points Concerning Its Diagnosis, Treatment, and Prognosis**

HELEN M. M. MACKAY, M.D., Lond., M.R.C.P.

London

The prognosis of meningococcal meningitis in infants and young children depends to a great extent upon the period at which treatment is begun; hence the great importance of early diagnosis, and unfortunately in sporadic cases diagnosis is usually late.

SYMPTOMS

It is now held that there is always a blood infection at the onset of this disease. The duration of the blood infection before the development of meningitis with its localizing signs may be extremely short—the two may appear coincident as in the fulminant type—or it may be of some days' duration, and not in every patient with meningococcal blood infection does meningitis develop. An interesting series of these cases came under my observation seven or eight years ago. In one child in a family, there developed typical meningococcal meningitis, the two others had pyrexial attacks. Of the latter, one rapidly recovered; in the other there developed arthritis of the knee and from the fluid in the joint the meningococcus was isolated. It seems probable that all these children had meningococci in the blood stream, though two escaped without meningitis. The most constant symptoms of the stage of bacteriemia appear to be pyrexia and vomiting.

Meningococcal meningitis is usually classified into three types—the fulminant type, the ordinary acute type, and the chronic or posterior basic type. The fulminant type with its profound toxemia and prostration is usually associated with an epidemic and is rare in infancy. The socalled ordinary acute type is a variable disease and it is consequently difficult to describe a typical case. The date of onset of the ill-

*A postgraduate lecture given in connection with the Fellowship of Medicine.

ness with pyrexia and vomiting is usually well marked, and symptoms of meningitis—headache, irritability, rigidity of the neck, and perhaps convulsions and squint—are coincident with or may develop shortly after the onset. Later in the disease, convulsions, muscular rigidity, and often tremors occur. The bowels are constipated. As the disease advances the back is usually arched, respirations are irregular, pulse poor and rapid. Occasionally there is a period of complete flaccidity. In an acute case treated early, there may be remarkably rapid recovery; without treatment, or with less successful treatment, recovery, if it occurs, is slow, or, following coma and emaciation, death may supervene in one or more weeks. This type is common in epidemics but is not the usual endemic type in infants. The frequency of skin lesions (herpes, petechiæ, or purpuric rashes) varies with the epidemic and possibly depends on the strain of meningococci present. The temperature is usually irregular. The respirations rate and pulse rate are often variable, as are the degree of rigidity and the presence of squint.

The chronic socalled posterior basic meningitis is the common form in infants, and in this type early diagnosis is usually difficult. The date of onset of the illness can generally be determined, but the early signs of meningitis are often indefinite, and may at first be absent, possibly because meningitis has not yet supervened on the blood infection. Among the many signs which may be present, stiffness of the muscles at the back of the neck and vomiting are perhaps the most useful and frequently present; there is usually constipation but this not infrequently changes to diarrhea as a result of an excessive dose of aperient or unsuitable food, and bulging of the fontanelles is an important sign but is occasionally absent throughout the illness. Neither absence of rigidity of the neck nor absence of a tense fontanelle excludes meningitis. The degree of pyrexia is often slight. A fit may occur at the onset but squint is generally a late sign. The difficulty of early diagnosis is illustrated by such a case as the following:

Case I.—James D., aged four months, was sent to hospital on the fourth day of illness with a diagnosis of scarlet fever. There was pyrexia, some vomiting, and there had been a transient rash. The fontanelle was never tense throughout the illness, and there was no stiffness of the neck until the eleventh day, when lumbar puncture was performed and the diagnosis of meningococcal meningitis established. The patient had ten lumbar punctures and seven doses of antimeningococcal serum given intrathecally, as well as vaccine treatment. By the thirty-eighth day he had grown considerably worse and had undulating respiration (almost Cheyne-Stokes) but thereafter improved rapidly. All rigidity had disappeared by the forty-ninth day. He was last seen at seven years of age and was then perfectly normal.

Though earlier diagnosis is often so difficult nothing is more typical than the disease when fully established, say in the third week or later, the stage so often illustrated in textbooks, when the child is unconscious or semiconscious, and lies on its side with general rigidity, arched back, retracted head, arms flexed, and adducted with thumbs under the flexed fingers. The legs are sometimes flexed, sometimes extended. Emaciation is progressive. The child may die at the end of two or three weeks or may go on week after week, with the head growing larger and the mental and physical condition worse, probably with periods of digestive upset and diarrhea. Blindness is common, nasal feeding may become necessary, and the child occasionally drags on for as long as six months. Gradual recovery, generally with aftereffects, does occur, however, in isolated cases.

DIFFERENTIAL DIAGNOSIS

Meningism.—Meningism is very common in infants, meningitis much less so, and for that reason early signs are often ignored, but in cerebrospinal meningitis the loss of every day in the diagnosis means a lessened chance of recovery. The diagnosis of an acute case of meningitis is often easy, but to avoid the likelihood of missing cases of the posterior basic type, one has constantly to bear the disease in mind and set out to exclude it.

When meningism is present but the signs are indefinite, as so often happens, careful search is necessary for any other cause of the meningism—a commencing lobar pneumonia, particularly apical pneumonia, otitis media, pyelitis, typhoid, even teething. But in the presence of meningism—vomiting, constipation, slight stiffness of the neck, irritability, with or without a bulging fontanelle or the occurrence of a fit—it is in the vast majority of cases wisest to perform lumbar puncture at once, as with proper precautions the risk attaching to lumbar puncture is almost negligible, and the importance of early diagnosis is very great. Such a rule of course would not hold if there were present, for example, early signs of apical pneumonia which is so often accompanied by meningism, but it appears quite unjustifiable to rest content with a diagnosis of, say, meningism from teething unless meningitis has been definitely excluded. Symptoms of meningeal irritation are often present in encephalitis or even poliomyelitis and in such cases lumbar puncture and examination of the cerebrospinal fluid will usually decide the diagnosis.

Once the presence of meningitis is diagnosed a provisional diagnosis of the nature of the infecting organism can sometimes be made from the history and clinical signs, though the diagnosis is not established of course until the causal organism has been found and identified. Pneumococcal meningitis, for example, is an acute and rapidly fatal form with sudden onset, often secondary to pneumonia and coming on in its later stages; streptococcal meningitis, also very acute, is nearly always secondary to bone disease, particularly middle ear disease. Tuberculous meningitis is more common after infancy than under eighteen months of age, the onset is less sudden, there is often a prodromal period leading up to a period of headache, vomiting, and fever, with perhaps a convulsion, and an x ray photograph of the child may practically clinch the diagnosis by revealing evidence of tuberculosis of the lungs.

Turning next to the character of the cerebrospinal fluid. In meningococcal meningitis it is almost invariably turbid, with a spontaneous clot on standing. There is generally reduction in the sugar con-

tent and the cells are usually nearly all polymorphonuclears. There is an easy clinical method of examining for diminution in sugar content in the cerebrospinal fluid which is insufficiently used. One cubic centimetre of normal cerebrospinal fluid almost completely reduces 0.1 c. c. of Fehling's solution, whereas if there is present a smaller amount of sugar than normal (as is usual in meningitis) the blue color of the Fehling solution still remains after boiling together one volume of solution and ten volumes of cerebrospinal fluid. The gram negative kidney shaped diplococci, intracellular and extracellular, can nearly always be found in direct films with careful search. They show up much more clearly in a methylene blue preparation than in the gram. When the organisms are very scanty, however, they may only be obtained in culture, or after incubating a test tube of the fluid for some hours. It is of great importance to remember that unless the fluid is kept warm the organisms will rapidly die and the opportunity of clinching the diagnosis and of determining the strain of meningococci present be lost. Sufficient warmth can be maintained by carrying the test tube containing the fluid in an inside breast pocket to the laboratory. An agar slant smeared with a platinum loopful of blood obtained from one's finger with aseptic precautions forms a very good culture medium.

If one withdraws a turbid fluid one is usually safe in assuming one is dealing with a case of meningitis, but there are certain pitfalls which are seldom noted but are the cause of many mistaken diagnoses. 1. If the needle has been kept in alcohol and perhaps merely dipped into sterile water before use, there may be sufficient alcohol in it to coagulate the albumen and so bring about turbidity of the cerebrospinal fluid and possibly blocking of the needle. 2. Again, once serum has been given intrathecally, the true character of the cerebrospinal fluid in the disease is masked, since serums—some in greater and some in less degree—set up a polymorphonuclear cell reaction, bringing about turbidity of the fluid, increased albumen content, and spontaneous clot. 3. A similar reaction may recur at the time of development of serum sickness, and be accompanied by signs of meningeal irritation suggesting a relapse. The presence of a serum rash may indicate the diagnosis in such cases, and it is generally stated that the sugar content of the fluid is unaffected by a serum reaction when it is reduced in meningitis. 4. The character of the fluid is often masked by the presence in it of blood due to injury of a vein at the time of a puncture. Fluid obtained from a puncture on the next day or two after such an injury is sometimes strawcolored from altered blood, and may give a fine cobweblike coagulum on standing, and so lead one falsely to suppose one is dealing with a case of tuberculous meningitis or possibly encephalitis. 5. Lastly, in certain cases, secondary for example to middle ear disease, there may occur a low "leak" of pus cells into the cerebrospinal fluid without a general inflammation and without organisms in the cerebrospinal fluid, but with these cases we are not concerned.

The leucocyte count of the blood is of little value in differential diagnosis, since most of the acute illnesses which may be associated with meningism, as well as all forms of meningitis, usually have a polymorphonuclear leucocytosis. It is, however, useful when the diagnosis lies between typhoid with its leucopenia and meningitis.

TREATMENT

Specific treatment.—Successful treatment is of course dependent upon a suitable serum being available. As yet no satisfactory method of standardizing these sera has been found, hence the clinician is largely dependent upon the method of clinical trial. However, on account of the different strains of meningococci, a serum which has given excellent results with one group of cases may not necessarily give good results with another. When facilities offer, it is desirable to have the type of the infecting organism determined, but as this may take two or three days (while a culture of sufficient growth to form a good emulsion for the agglutination test is obtained) it is essential to use a polyvalent serum in the first instance, though later a "type" serum may be substituted if obtainable.

An anesthetic should, in my opinion, be disposed with whenever possible for the operation of lumbar puncture; it is seldom necessary in the case of small children and never for infants as they can be held steady. An anesthetic may mask the signs that sufficient fluid has been drawn off, and so be a danger, and, more important, it always causes unnecessary disturbance to the feeding and general condition—a point of primary importance in a wasting illness in which lumbar puncture may be required daily for many days.

If, from the clinical picture at the time lumbar puncture is first performed, meningococcal meningitis appears a likely diagnosis, a phial of polyvalent antimeningococcal serum should be warmed to about blood heat in water while the lumbar puncture is being carried out, and, if the fluid obtained is turbid, serum should be injected without waiting for its bacteriological examination. This is recommended because if the case should turn out to be, say, pneumococcal or primary streptococcal meningitis, it will in any case almost certainly prove fatal; if it is meningococcal meningitis the prognosis depends largely on how early in the disease serum is administered.

The amount of fluid drawn off will depend on the degree of pressure and the condition of the child—its color, pulse, respirations, and the condition of the fontanelles. The amount of serum given to an infant at one dose will probably not exceed fifteen c. c., and it is generally agreed should never exceed in volume the amount of fluid withdrawn. If it is given extremely slowly there seems no objection to giving it with a record syringe instead of by the gravity method. After the intrathecal injection the foot of the bed should be tipped or the child's buttocks propped up. This is probably the most useful means of combating the shock which may be present, and it presumably assists the serum to reach the ventricles.

Occasionally the serum produces a toxic reaction, and such serums have to be discarded. If there is no contraindication, it is my practice to repeat lumbar puncture at first daily, and later every second day, for as long as the fluid is under excessive pressure,

remembering that excessive pressure alone will quickly cause irreparable damage to the brain. The administration of serum is repeated daily until no organisms can be found in the direct film of the fluid or grown in cultures. The most frequent contraindication is a distinct worsening in the child's condition after the operation, in which case it will usually be necessary to seek another less toxic serum. The possibility of anaphylaxis has to be borne in mind if it is desired to give an injection of serum after a week's interval for a relapse, and in such cases it would be wise, with a view to desensitizing the patient, to give in the first instances about one c. c. hypodermically, and to wait six hours as is usually done in cases of diphtheria.

When intrathecal pressure is not excessive one may easily fail to obtain fluid by lumbar puncture in an infant, even when there is no block to the circulation of the fluid. Much depends upon having a fine needle with a really sharp point. If no fluid or only a few drops can be obtained after several attempts, one may with infants fall back on ventricle puncture. This is an extremely easy operation if the pressure is great and the fontanelle is bulging, with only a thin layer of brain substance above the lateral ventricle, but there is always a certain risk of damage to the brain thereby. To avoid unnecessary injury the head must be kept steady, and this should be the whole duty of one assistant. A small bore needle with a light head should be used, and gently supported all the time it is in position to prevent all avoidable movement in the soft brain substance. The puncture is usually made in the outer angle of the anterior fontanelle about three quarters to one inch from the midline, and the direction of the puncture aiming a little in front of the ear.

GENERAL MANAGEMENT

The feeding in cases of posterior basic meningitis is often difficult, and there is grave risk in infants of setting up an intractable diarrhea with unsuitable food or aperient. If swallowing becomes impossible, nasal feeding may be necessary. A case is described below in which the patient recovered after forty-five days' nasal feeding, during half of which time he could not swallow at all. Consequently the illness should never be considered hopeless because of inability to swallow.

The patients are difficult to nurse, and require great attention to avoid bedsores, intertrigo of the rigidly flexed hand, or stomatitis, and to prevent the occurrence of contractures during convalescence.

PROGNOSIS

Prognosis in the average case of posterior basic meningitis appears impossible, but everyone dealing with such cases requires to remember the extraordinary recoveries sometimes made in apparently hopeless cases. The percentage of recoveries in a group of cases will depend very largely upon the availability of a serum suitable for the particular strain of meningococci prevalent; but the number of fatal cases and of cases with serious sequelæ (hydrocephalus, mental defects, spasticity, paresis, and loss of hearing or vision) is always very high.

An acute case of meningitis treated early may make a very rapid recovery—witness a boy brought into hospital unconscious, and given serum, who within forty-eight hours was heard to greet his mother in a new hat with "Hullo, some hat." In the more chronic posterior basic case, however, when recovery does take place, the progress is usually extremely slow, the rigidity may persist for months, and not infrequently the child gradually relearns to sit up, walk, and speak like an infant learning for the first time, though recovery even in such cases may be complete.

Case II.—Ernest W., aged four years, was admitted on the twenty-third day of his illness, unconscious, back arched, head retracted, limbs flaccid. Twenty-five lumbar punctures were performed in all, the last on the seventy-third day of his illness, thirty to sixty c. c. being withdrawn each time. Nine doses of serum were given, and also an autogenous vaccine. Prognosis was bad for about two and one half months after admission; the occiput was touching the back, there was extreme emaciation with rigidity, strabismus, incessant twitching of the right side of the face, arm, and leg for days on end, and for forty-five days nasal feeding had to be resorted to. On the eighty-eighth day of illness the child swallowed again for the first time, and from that date put on weight and became later enormously stout with a remarkably thick coat of hair over the limbs and trunk. Five and a half months after the onset he still lay, taking no notice of anything, like a log in bed, with intervals during which he screamed for hours at a time. He was sent out of hospital, and the mother gave an account of how the child began gradually to take notice of and then learned to know her, to recognize objects, and to speak "like a baby learning for the first time." It was nearly a year from the onset of the illness before he relearned to walk. Two years after the onset he was still using the right hand very little, though there was no paralysis and no aftereffects remained in the right side of the face or right leg. At this age he was intelligent enough to do simple shopping errands for his mother. Now, at ten years of age, he is going to a school for backward children and is "no use at bookwork" but is intelligent enough to be very useful to his mother in the house. He has recently suffered from fits.

Even in cases which have required ventricle puncture the patients may make remarkable recoveries.

Case III.—Mary S., aged five months, was admitted on the tenth day of her illness, with early signs. Lumbar puncture was attempted seven times in all, only twice was any fluid obtained, though the fontanelle was bulging greatly after the first few days in hospital. Twenty-one ventricle punctures were performed, fifty to one hundred c. c. being withdrawn on each occasion, the last on the fifty-third day of the illness. Four doses of serum were given. After the last lumbar puncture there was for four or five days a leak from the ventricle through the puncture wound—in sufficient quantity to soak a large pad of wool in a few hours—and to my surprise, from that time the child began to improve and the head circumference diminished. There was head retraction for about four and one half months from the onset. When two years and nine months old, when last seen, the child, though talking moderately well, was backward for her age. This

was due, in part at least, to the physical retardation brought about by rickets of some severity; the mental improvement had been marked after treatment for rickets was begun. There was strabismus, but no other physical defect traceable to the attack of meningitis.

Strabismus is a common sequela of meningitis, and nerve deafness not uncommon. Some patients may have normal intelligence and learn to lip read; some are deaf mutes.

Prognosis is complicated not only by the extraordinary recoveries in some of these cases, but by the fact that aftereffects occasionally develop long after the attack; for example, in Case II the patient began to suffer from fits over five years after the onset of meningitis.

Then again sudden death occasionally occurs a considerable time after the illness, even though there has been apparently complete recovery. The following is presumably a case of this class:

CASE IV.—Arthur M., aged eight months. Admitted twenty-first day of illness, deeply unconscious with rigidity, squint, unequal pupils, and head retraction. Lumbar puncture with the injection of serum was performed daily for seven days, thereafter puncture was dry or nearly dry. There was difficulty in swallowing and progressive wasting after admission, and food by mouth was supplemented by nasal feeding for over six weeks. On the fiftieth day the occiput was still touching the back. Nearly three and one half months after the onset the child was still taking little notice, was unable to sit up, and had slight head retraction. About five months after the onset, at one year old, he was taking an interest in his surroundings and all rigidity had gone. He did not walk steadily until two and one half years old. When seen at three years and two months and again at seven years old he appeared a perfectly normal and especially alert and intelligent child. Shortly after this date he died very suddenly one night in his own home. No history could be obtained suggestive of a fit.

CONCLUSIONS

From the cases quoted it is obvious that when treating a case of posterior basic meningitis one should never allow the child's attendants to give up hope—though on the other hand even in the cases seen early with few signs one cannot give a good prognosis. Prognosis will depend on such factors as, 1, the availability of a suitable serum; 2, stage of the disease at which it is diagnosed; 3, measures taken to prevent so far as possible irreparable damage to the brain from excessive intracranial pressure; and 4, last but by no means least, the skill of the nursing and the tenacity of the medical attendant and nurse.

A Case of Vascular Nevus in an Infant Treated With Radium*

A. W. JACOBS, M.D.
New York

It is generally known that radium is a valuable agent in the treatment of vascular nevi. The case reported is of interest firstly, because it shows the necessity of persistence in treatment, and secondly, that radium though applied to such close proximity to the eye has shown no deleterious effects upon the tissues of the eye.

CASE.—G. S., aged eleven weeks. Was brought to the Montefiore Hospital Radium Clinic on October 10, 1923, with the following history: Premature birth (eight months). Breech presentation. Birth weight four pounds six ounces. Breast fed every three hours. About one and a half weeks after birth mother noticed a small red spot about the size of a small pea over the inner canthus of left eye. Has been increasing in size and continued to become a brighter red in color.

FIG. 1.—Case of vascular nevus before treatment.

FIG. 2.—Same case as in Fig. 1, after treatment.

Physical examination showed a well nourished, vigorous, female infant weighing seven pounds seven ounces. Local condition showed an elevated, pinkish, red mass about one and a half by one half cm. in size, located just above the inner canthus of left eye. The lesion was treated weekly with radium applied to the lesion in an applicator, screened with one half mm. brass and one half cm. gauze filtration, average being fifteen cm. of radium emanation applied for three hours. The first treatment was given on October 14, 1923, and the last treatment on February 17, 1924, making a total of fifteen treatments. Ophthalmological examination after the series of treatments shows the eye to be in normal condition. At present there is a pale white area over the site of the original lesion as shown in the photograph of the infant at the age of eight months.

125 WEST SEVENTY-SECOND STREET.

Historical Medicine

Concerning the Physiological and Therapeutic Rôle Played by Animal Testicular Extract as Shown in a Number of Cases in Man*

M. BROWN SÉQUARD

Translated from *Archives de Physiologie*, Series 1, 1889, page 739, by L. L. Stanley, M. D., San Quentin, California

Since the experiments which I have made upon myself have been published, the public press of both continents have printed a great deal without knowing anything about them (*on a parlé sans les connaitre*), and unfortunately has awakened in thousands of people weakened by age, sexual abuses and other infirmities, absurd hopes which are to be promptly discarded. In the United States especially, often without knowing anything about what I have done, nor the most elementary rules in regard to subcutaneous injections of animal material, many doctors, or rather unauthorized practitioners, quacks and charlatans, have exploited the ardent desires of a great number of people and have subjected them at least to the greatest risks if they have not done worse.

I should like to be able to tell what the results have been from thousands of injections of testicular extract which have been made in America and other places.

Unfortunately the principal elements of a serious appreciation of the subject are almost completely lacking, chiefly because I do not know anything about the work of most of the physicians of the United States except from the articles of reporters in the public press.

I shall point out presently the works published by a certain number of physicians; but it is important to be able to compare them with those other observers whom I would like to make understand the results of the experiments which I made upon myself and which were reported in another communication.

The thought which led me to do these experiments was that the weakness of old age depended in part on a diminution of the activity of the spermatic glands. I have believed and still believe that the facts which I have reported give proof that the vigor of the nerve centres and other parts of the organism is linked with the secretory powers (*la puissance secrétoire*) of the testicles. Admitting this to be true, it is entirely natural to think that in giving to the blood of an old man, by subcutaneous injections, a liquid extracted from young and vigorous animals, one might succeed in making up for the insufficiency of his spermatic secretion. It was also reasonable to believe that in addition to this special influence, the injected fluid would also increase the secretion of the testicles.

It seemed, according to the reports made by authentic physicians, that this special effect had been obtained with old men, as well as with men still young, who had been weakened by excessive venery.

Some have thought that all the action of certain elements of the injected liquid consisted in a stimulation of the nerve centres or other parts. In fact, it would be necessary to forget completely the most simple ideas about the action of physical agents, of medicaments and of poisons upon the animal organism, to accept such an opinion. In truth we know that two kinds of effects can be produced by these agents or substances; one consisting of a stimulation followed by putting into play (*mise en jeu*) the part irritated; the other consisting in an increase or diminution of the power of action. In all the changes which I have shown to have taken place in me, there has not been a putting into play of any power, and moreover, these changes have lasted whole weeks, and there is one which is lasting even up to today, more than three and one half months after the last injection; that is, the improvement in defecation which is sufficient to show absolutely that stimulation is not the cause of the changes. It is clear that that which has taken place is an increase in the power of action. What remains to be decided is to know whether it is true generation of physical power (*dynamogénie*), that is to say, a purely dynamic change which has taken place. Some of the effects are so prompt in appearing that it seems probable that for them at least it is that which does take place (*c'est là ce qui se produit*). But other effects are rather slow and it appears certain that it is the result of an improved nutritive action, that is, an organic change where the force is increased in certain parts. The liquid extracted from the male sexual glands probably therefore will act on some organs in producing a pure generation of force (*dynamogénie*) and in others by activating nutrition.

Great ignorance is shown by those who hold that it is impossible for old men to return to a better organic condition or a condition of health such as they had at a younger age, because organic changes, due to an improvement in nutrition, are possible at all ages. I do not wish to discuss today the question of knowing what are the substances contained in the injected liquid to which the effects are due. Numerous experiments ought to be made to obtain the solution of that problem. All I can say is that the spermatozoids (*les animalcules spermatiques*), which have a special physiological rôle, had no dynamogenic influence on the liquid used in my experiments for these solid particles do not pass through the Pasteur filter. Of this M. Henocque is positively sure.

I ought to say that I know, having studied it with care, an extremely remarkable and conclusive case which demonstrates that the spermatozoids are not a part of the liquid secreted by the testicles which gives to man the various physical, mental and intellectual activities that are lacking in the eunuch. In fact, in an officer, outstanding for his vigor and other mental and physical qualities and also for his sexual pro-

pensities and the quantity of sperm which he produced, there was entirely lacking the spermatozoids in his secretion. Professor Cornil has been convinced of this for a long time and M. Henocque and myself more recently. Besides it is probable, a priori, that the spermatozoids did not participate in the dynamogenic action of my injections. Although we know that they cannot be absorbed and that it is the liquid part of the sperm which, being absorbed, is the vivifying agent of old and young individuals who have active testicles.

All that I wished to obtain by previous publication was that other aged doctors and physiologists would do upon themselves experiments similar to mine. Only two in Paris have made such tests. Their results have generally been favorable. Of them I will speak presently. Unfortunately the effects produced have not been sufficiently studied.

In the many observations published already, particularly those of Dr. Variot, of Paris, Dr. Villeneuve, of Marseilles, and Dr. Loomis, of New York, the persons treated have been studied only a certain period of time. One is assured that certain good effects have been produced and after one or two weeks they have not been studied further.

There are two phases to the influence exerted by a liquid extract of the testicles; one consists purely and simply of the physiological effects which it produces and the other in the researches for the therapeutic effects. No one has yet to my knowledge made, either separately or together, a study of these two kinds of manifestations. One would have to find out among old men of good health what the effects produced really are; that unfortunately has not been done. My greatest aim now is to cure disease. Checks or obstacles which one expects have been forthcoming, and successes except in some cases have not been sufficiently established.

Doctor Variot has the credit of being the first to study in old men the action of the fluid taken from the testicles with the end in view of assuring himself that that which I have found in myself would manifest itself in other people. I can only mention here briefly that which he has found.

OBSERVATION I

A man, aged fifty-four, afflicted with anemia and chronic diarrhea. He was given two injections of testicular liquid. That evening unusual feelings of well being (*sensations de bien-être*) which lasted during the next day. He had, he stated, a clearer head, more supple limbs and more vitality. His vision was more acute and he could walk without fatigue. His lost sexual power returned.

OBSERVATION II

A man, aged fifty-six, who could hardly stand upright nor walk a few moments without being obliged to sit down. After three injections he acquired considerable vitality, became jolly, full of spirits, and appetite greatly increased.

OBSERVATION III

A man, sixty-eight years of age, who could scarcely leave his bed. The day following the two injections he walked with pleasure and felt much stronger. Appetite was greatly increased. Morning erections were intense. He had had none before in two months. Bowel movements became possible without enema.

Since M. Variot published his three cases (*Comptes rendus de la Société de biologie,* 5, Juillet, 1889) he employed injections of testicular extract of the rabbit and guineapig in a number of other diseases. It is not possible to give an analysis of all these cases some of which have been negative. I will mention only four or five.

Among Variot's cases, the most important was that of a physician aged sixty, who after a course at Vichy was excessively feeble and felt entirely tired out. According to his own statement he had gained considerable in mental activity and in strength of muscles as well as sexual powers after only four injections, two each day. That was last August. He wrote me, under date of October 6th, saying that the good effects had continued, although he had not had any further injections.

Another case was that of a doctor in Paris, aged thirty-five years, who was afflicted with sexual impotence and of very great weakness. After six injections there was an increase of strength and the ability to have sexual relations.

In an old man, eighty-one and a half years old, without marked infirmity, there was no noticeable effect of the injections until after some weeks, when he wrote to Dr. Variot that the injections had been a complete success with him, particularly the last two. He felt, he said, a great increase in power in all respects, as if he was only about twenty to twenty-five years of age.

In one control experiment Dr. Variot made two injections with a fluid stained with blood, and he stated that the patient, aged fifty-eight, afflicted with diarrhea and bronchitis, did not experience any good effects. Without letting it be known to the patient what was being given, a liquid taken from an animal testicle was injected and from the day following he affirmed that he was very much better, that his brain was clearer and that he experienced a feeling of unusual well being. Erections had returned two weeks after the last injection. He said that he was put back on his feet by that injection and the good effects still persisted at the end of six weeks.

An interesting work has been published by one of the most distinguished physicians of New York, Dr. H. P. Loomis (*Medical Record,* August 24, 1889), reporting the results of the injections extracted from testicles of the ram. Unfortunately, these injections, as those made by other doctors who have repeated my experiments, have been made almost exclusively on sick people. The favorable cases have been those of men aged fifty-six, sixty-two, and seventy-seven years, the most remarkable of all. Seven other patients have not had any good effects nor have had their disease made worse. That took place in one case of rheumatism and one case of locomotor ataxia. (1)

I will only say a word about the report of a well known physician, W. A. Hammond (*New York Medical Journal,* August 31, 1889, pp. 272). This work contains nine observations, one where the in-

[1] I know of five cases of locomotor ataxia besides those reported by Dr. Loomis, where the injections of testicular extract have been used. The disease was not increased in any of them but in two there was no change in the condition. In two there was slight improvement and in the fifth a very considerable amelioration.

jection was made on a woman, all showing extremely favorable results, not only in cases of infirmities but various diseases and even in certain affections of the heart.

Another American, Dr. Brainard, of Cleveland, up to the fifteenth of last August used the injections on twenty-five people, five of whom were women. Most of them were ill and extremely favorable effects have been obtained in almost all of them. The extract was taken from rams, as in the cases of Dr. Loomis and Dr. Hammond.

I have received from Dr. Grigorescu, of Bucharest, two reports partially favorable. These proofs which I have and a number of others do not permit me to suppose that that which I have observed upon myself has depended in part or entirely upon a special idiosyncrasy or an auto suggestion.

In spite of a lack of details in all observations so far published and in spite of the number of criticisms which undoubtedly deserve to be given to a great number of them, there is nevertheless evidence that the testicular extract as employed has produced upon the nerve centres all the dynamogenic effects which I have observed upon myself and others as well.

There is nothing to show that they do not exist, but I repeat that the effects as shown by me have been observed a great number of times. Other dynamogenic phenomena have also been found with those who were ill and especially in cases of weakness of the heart action.

It is therefore without doubt that subcutaneous injections of diluted fluid extracted from testicles of animals living or those just killed exert a considerable dynamogenic effect on the nerve centres, at least in a large number of persons. It cannot be doubted likewise that these injections are harmless if they are made with all the precautions which capable physicians know to be essential when they introduce under the skin any animal product (*matières animales*).

The London School of Medicine for Women

A Retrospect

For fifty years the London School of Medicine for Women has been giving medical education to women and sending its graduated students out to do work of a very varied kind in private practice, in clinics and schools for mothers, as specialists and, perhaps most important, as workers among the women of India whose religious or caste rules do not allow of their being treated by men. Medical women have devoted themselves with few exceptions to the service of their own sex and have succeeded in gaining the confidence of thousands.

They have created the demand, they have provided the supply and during those fifty years they have borne themselves with dignity and done their chosen work with ability; so that now, at the close of their half century, they are celebrating the jubilee of their own school and asking that those who know the value of what they have done should help them to found three chairs in that school to the memory of three great pioneer women in medicine: Elizabeth Blackwell, Elizabeth Garrett Anderson and Sophia Jex-Blake.

Mary Scharlieb, the doyenne of medical women, is now president of the school. She has had a wide experience covering almost every kind of work done by the medical women of the present and the past—from attending the purdah women in the East to private practice in the aristocratic precincts of Harley Street. She is justly proud of the position which the school holds today. Looking back over the fifty years of medicine in the course of an interview she recalled her own beginning of work in Madras. When she was a married woman with children and was helping her husband, who was a barrister, it fell to her lot to review a monograph on Medical Jurisprudence for the *Madras Jurist* and thus her interest was first aroused in medicine. At the same time she was constantly hearing of the sufferings of Hindu and Mahommedan women in sickness and in childbirth when, owing to purdah rules, they could not have a male physician to attend them. There was one terrible incident of a young Mahommedan lady, no more than a child in years, whose husband, unable to bear the sight of her sufferings, sent for a European surgeon to relieve her. The poor child dragged herself to the door of her room so as physically to prevent his entrance and died in that position.

This incident had a profound effect on Mrs. Scharlieb. "I felt," she said, "that there ought to be European women doctors qualified to deal with such cases and I began to study midwifery privately in 1870. Desiring to get practical training I was introduced to Surgeon-General Balfour, the head of the Medical Service in Madras, and through him to Surgeon-Major Cockerill, the superintendent of the Lying-In Hospital. He was a weary looking man with Dundreary whiskers but an excellent officer and a good obstetrician. He was sceptical of my strength of will and perseverance. 'You won't like it,' he said, 'it is very dirty work.' I told him my clothes would wash. 'Your husband won't like it' was his next objection. 'If my husband did not like it, I could not be here,' was my answer.

"He then objected that my health would not stand it and, finding nothing shook my determination, he asked would I nurse any case that might be given to me. When I said I would, he brought me out in the blazing sunshine to a leaf pavilion in the hospital compound and there I saw lying on a cot what looked like a small hippopotamus. It was a woman so swollen that she was hardly recognizable. 'Will you nurse her?' he said. 'It is the worst case of confluent smallpox I have ever seen.' 'Yes,' I said, 'I am quite prepared.'

"When the Surgeon General asked me later how

The London (Royal Free Hospital) School of Medicine for Women (University of London). Founded in 1874.

I had dared to accept Surgeon Major Cockerill's challenge I told him for two reasons—I had been revaccinated the week before, and I did not believe he would hand such a case to a beginner; and I was right, for the woman died that night."

And so began Dr. Scharlieb's training in duty at the hospital from 6 a. m. to 6 p. m. After a year she found that a knowledge of midwifery and the diseases of women was not sufficient to make her a really useful adviser to Hindu and Mahommedan women and that a knowledge of general medicine and surgery was also necessary. This was the time that the agitation which led to the formation of a school of medicine for women was going on in England, but family circumstances prevented Mrs. Scharlieb from immediately returning to take part in the movement. Instead, she secured the interest of the Governor of Madras, Lord Hobart, and of Surgeon General Balfour, in a scheme for the provision of medical women for caste and Gosha women. Four women, of whom Mrs. Scharlieb was one, enrolled themselves as students of the Madras Medical College for the winter session of 1875. And that event was as sensational in its own way and perhaps meant as much to the women of India as did the opening of the London School of Medicine for Women in 1874. The Government of Madras saw the necessity for medical women and made arrangements for them on a generous scale; they paid no fees, textbooks were given to them and a room at the Medical College was assigned to them. They shared in the instruction given to the young men who were preparing to be assistant surgeons and sub-assistant surgeons in military and civil employment under the government of Madras. Their practical midwifery was taken at the Lying-In Hospital and other clinical work at the Women's Hospital. At the end of three years the four students received the Licentiate of Medicine, Surgery, and Midwifery from the Madras Medical College and then Mrs. Scharlieb, who had secured admission to the General Hospital in Madras because the teaching arrangements there were sufficient to satisfy the requirements of the University of London, returned home to take the M. B., B. S., degrees. From that time her history merges into that of the London School, and she passed through the strenuous curriculum. When she received the gold medal and scholarship for Obstetric Medicine in the final M. B., B. S., the examiners were the late Dr. Mathews Duncan and the late Dr. Gervis. The latter is said to have remarked: "Oh, to think I have lived to give the scholarship in my own subject to a woman. But there, it was an excellent paper and it can't be helped!"

Mrs. Scharlieb went to Vienna for operative midwifery on the living preparatory to her work in India and on her return received a summons to go to Windsor to see Queen Victoria. The Queen asked for the truth about her women subjects in India and got it. Mrs. Scharlieb told her at length of the sufferings of caste and Gosha women owing to the impossibility of their being attended by men doctors and of the frequent failure of the methods of the native midwives. When she had heard this, Queen Victoria turned to her lady in waiting and said "How can they tell me there is no need for medical women in India?" And then this great Queen, who

was herself against any emancipation that she thought would lower the social prestige of her sex, gave Dr. Scharlieb this message for her Indian patients—"Tell them how deeply their Queen sympathizes with them and how glad she is they should have medical women to help them in their times of need." She added, "I will give you my photograph and you must take it with you to their houses to show them how much I feel for them." And that photo in its heavy gilt frame was a talisman for years in India.

Until February, 1887, Mrs. Scharlieb remained in practice in India, where she was lecturer on Midwifery and Gynecology and the Diseases of Children at her old college. She was also Medical Superintendent of the Royal Victoria Caste and Gosha Hospital until her health broke down and she returned to England. There her later history is well known. She was appointed one of the surgeons of the New Hospital for Women (now the Elizabeth Garrett Anderson Hospital) and subsequently to the Royal Free Hospital. This was the only one of the twelve great London hospitals to which no male medical school was attached; in 1877 it admitted women to clinical practice in its wards, thus beginning its connection with the London School which has lasted ever since.

Dr. Scharlieb's views on women physicians and surgeons are distinguished by strong common sense. She makes no undue claims for them. She thinks that in work among women and children is their greatest sphere. "There is a strong demand for women doctors," she said, "a woman in childbirth who has been attended by a woman will seldom have a man again, and many men doctors in cases of women's diseases send their patients to a woman doctor. I have always been good friends with my male colleagues—I have a son a doctor—I see their goodness, their kindness and their skill; but I am not prepared to admit that women do not possess the same qualities, and the curious thing is that there are more women skilled as surgeons than as physicians—which is not what the public would expect. I have perfect confidence in the future of medical women. They are being more and more utilized in the public services, they are in growing demand as general practitioners, for the running of philanthropic enterprises and as medical missionaries. If the young women coming into the profession play the game honestly and devote themselves to their work, comporting themselves with dignity in their student days and preparing themselves for a life which will try them and make many demands upon their personality as well as on their skill, they will have nothing to fear.

"I think it is a good thing for women to keep to their own school," she went on. "At the present time I do not approve of mixed schools—not for the foolish reasons often assigned but because the authorities will always naturally prefer the young men to the young women when it comes to those appointments on the senior staff which give experience, opportunity and prestige. From this point of view it is a waste of time for a woman to be working at a mixed school where she can never rise to the top. At the Royal Free Hospital there is a mixed teaching staff and women share the senior posts with the men. At the Women's Hospitals the entire staff are women; for this reason it seems better for the young students to go where they will have fuller opportunities."

William Bullein.—"William Bullein was an English physician, botanist, and ecclesiastic of the middle of the sixteenth century, to whose ill fortune we are indebted for a most interesting book," writes Dr. Alfred J. Brown in *Surgery, Gynecology and Obstetrics,* February, 1925. "He was born on the island of Ely during the early part of the reign of Henry VIII, and died in London in 1576. His early education was gained either at Oxford or Cambridge, or possibly both. Later he studied for the ministry and for four years held a rectorate in Suffolk. He practised for a time in Durham and then moved to London, where he attained considerable reputation.

"In 1548 he published a book which was called *The Government of Health,* which was reprinted ten years later. In this reprint he promised to publish another book in a year, referring to his *Bulwarke.* This he wrote, but the copy was lost in a shipwreck. In the meantime William Hilton, a brother of Sir Thomas, the Baron of Hilton, to whom *The Government of Health* was dedicated, brought against Bullein the charge that he had murdered one of his patients. This kept Bullein under surveillance for a time, and then, the accusation failing, Hilton had him imprisoned for debt. He was later found not guilty of this charge and freed.

"The lay literature of the time frequently used dialogue as a means of expression and Bullein borrowed this method in his surgical treatise; the sick man and the surgeon carry on a conversation regarding various surgical conditions. In the first part of the dialogue the surgeon tells the sick man what surgery is and what the surgeon should be. It contains a diatribe against untrained and irregular practitioners. Some of these he characterizes 'like as the swarmes of vagabound Egyptians.' He says they travel from town to town 'with a box of salve, and cases of Tooles' and when they can get nothing else: 'Then fall they to Palmistry, and telling of fortunes, dayly deceiving the symple.' He defines surgery as an art rather than a science and divides it into two parts, the first 'Theorica' and the second, dependent on the first, 'Practica.'

"Bullein's characterization of the requirements of a surgeon are given as follows: 'Eight things or propertyes of a good Chirurgian. He must begin first in youth with good learning, and exercise in thys noble arte, he also myst be clenly, nimble handed, sharpe sighted, pregnant witted, bolde sprited, clenly apparayled, pytefull harted, but not womanly affectionated to weepe or trimble, when he seeeth broken bones, or blouddy woundes, neyther must hee gieve place to the cry of hys soare pacient, for soft Chirurgians maketh fowle soares. Of the other syde, he may not play the partes of a Butcher to cut, rend, or teare the body of man kinde. For although it be frayle, soare, and weake, yet it is the pleasure of God, to call it hys Temple, hys Instrument, and dewelling place, and the Philosopher doth call it Orbiculus, that is a little world.'"

PRESERVATION OF THE UNFIT

Those who have studied the history of the human race in its evolution have noted the way in which periods of great privation are followed by migrations which in themselves constitute further hardships. The migrants, once they have reached a suitable environment, tend to progress physically, economically and culturally but after a time retrogression begins to take place; the descendants of the sturdy pioneers who braved hunger and all the forces of nature become weaklings and hence are the prey of some ruder, stronger civilization. The original migration killed off all except the strongest of mind, body and character; the racial stock was improved and was able to maintain its supremacy until a period of security and prosperity permitted the substandard members of the tribe to reproduce and increase in numbers. When the point was reached where this group was larger than the number of the virile and intelligent, the race was doomed to extinction, subjugation or migration. It was the old story of the ascendancy of the fit over the unfit, the oft repeated tale of the manner in which the forces of evolution operate by selecting the best of a stock for preservation and discarding the weaker brains and bodies.

This process is going on in America today. In spite of the difficulties imposed by our immigration laws a constant stream of other races is entering the favorable environment of the United States and it is safe to say that the number of clandestine entries exceeds those admitted legally and probably is better stock than those who come in the ordinary way. A considerable degree of fortitude, persistence, foresight and physical resistance is necessary to elude the vigilance of the immigration officials, cross the borders of the nation and effect a settlement in a land of alien speech, customs and conditions. It is no wonder that the descendants of these people make rapid economic, cultural and social progress. Any voluntary migration, no matter how many improvements have been made in transportation, requires a certain amount of determination and physical strength and those who migrate are generally hardier and of better mental fibre than those who stay at home.

The sufferings and poverty of the settler and the first generation are generally severe and the process of adjustment to new conditions of industry and life weeds out many of the ineffectives. Thus the ruthless forces of Nature, by sheer brutality, improve the character of the stock.

In the United States there is going on also an intranational migration. There is a constant flow from the older settlements of the Atlantic seaboard into the less thickly populated portions of the United States and stocks which have undergone deterioration in the effete East blossom again in the more rigorous atmosphere of the younger states.

In the meantime, what is to become of the weaklings and defectives which are being bred in the security of an older civilization? It is not entirely because of improved methods of diagnosis that the number of persons confined to institutions for the care of the insane has increased so rapidly. Had the same proportion of mental alienation persisted in the original settlers of North America, the United States would never have been. In the hard days of conquering the new land, the weaker elements among the colonists perished; today they are safeguarded, protected and permitted to reproduce their kind.

This raises an important question. Is public health and the great humanitarian movement of today attempting by the conservation of fit and unfit alike to turn aside the great evolutionary forces of Nature? The modern tendency is to give to the defective even greater attention and care than is accorded to the normal: every effort is made to preserve the abnormal child, to render it selfsustaining in adult life and to safeguard its children. This may be of temporary benefit to the economics of the present, it may improve community character by indoctrinating kindliness and charity but what of the economics and character of the future when the defectives are in the majority?

Man is groping after the solution of this problem. Genetics, the birth control movement, the prophylaxis of syphilis—that arch creator of defectives—prenatal hygiene, the sterilization of the insane and the various methods being put into force for the maintenance of a physically and mentally rugged stock act to a certain extent to ward off racial deterioration but the conservation of the less fit continues and is being aided by sanitarians. Does the good work which public hygiene is doing overbalance the potential injury to the racial stock which may accrue from the perpetuation of the poorer strains? Scattered over the Western Hemisphere are the monuments of once flourishing civilizations which have absolutely disappeared. Is this going to happen again?

Evolution is inexorable; it permits no race to stand still. Man must go forward or backward or be exterminated. If he is sufficiently intelligent, if he has adequate selfcontrol, he may possibly turn this ruth-

less force to his betterment. Lacking these qualities, the dominant races of today will not escape the ruthless law that man must progress or retrograde, migrate or undergo subjugation and extermination.

CHANGING VIEWS AS TO DIET

Medical opinion with regard to diet has changed considerably during the past few years, and is still changing. It is now almost an article of medical faith that a diet should consist of food containing the usual food constituents of civilized life in due proportion, and especially the mineral salts, modified and regulated with regard to climate, occupation, and so on. Also the personal equation must be always considered. There is no more true saying than that "one man's meat is another man's poison." Views regarding diet are changing chiefly with respect to the sophisticated foods of civilization and it seems to be becoming more and more evident that the somewhat primitive methods of preparing and cooking food are better adapted to the establishment and preservation of sound health. Whole wheat bread, for instance, in which the husk has been left and in which close milling has not refined away many of the most nutritive properties, is a more healthful food than the very white highly milled bread which is generally put before one in restaurants. Such a bread is not only more nutritious, but on account of its rough content, favors peristalsis and is a remedy for constipation, one of the greatest banes of modern life. Again, too long cooking or cooking at a high temperature is a fault of civilization; much of the nutritious effect of food is spoiled or impaired by too great heat or by heat too long continued.

The importance of the vitamine element in diet appears to have been established firmly, although there are those who refer to these elusive substances as hypothetical and state that if the mineral salts are present in their correct quantities, the vitamines will take care of themselves. However, this statement does not mean that the vitamines are not essential, but that if the necessary amounts of mineral salts are supplied, these will contain the essential vitamines. Fresh vegetables and uncooked fruit are other articles which are indicated in a healthy diet, more particularly perhaps for those who lead a somewhat sedentary life. Vitamine A is contained in green vegetables, spinach and cabbage, carrots and cereals. Vitamine B not only includes the antineuritic vitamine found in rice polishings, but a water soluble, growth promoting substance found in a number of foods. It is not readily destroyed by heat or oxidation and is said to stimulate glandular matabolism and to be concerned in carbohydrate metabolism. It is found in cereals, nuts, tomatoes, lemons, oranges, vegetables. Vitamine C, known as the antiscorbutic vitamine, is contained in raspberries, oranges, lemons, tomatoes, carrots, legumes, lettuce, onions, greens, and sprouting grains. A high temperature applied for a short time is less destructive to this vitamine than moderate heat applied for a long time.

From a consideration of the diet question from the viewpoint of the vitamine, two or three points stand out prominently. It is conceded that a certain quantity of the various vitamine elements is essential for continued good health, and it is further known that a high temperature will injure one vitamine and a continued moderate temperature will impair the nutritive properties of another, while heat has less effect on yet another. Yet cooking injures to a greater or less extent the nutritive and stimulating properties of all foods, and consequently the practice of eating daily some fresh fruit tends to establish and maintain good health. It is a long practised custom of civilization to cook food, often to cook it too much. It is then an act of wisdom to neutralize as far as is possible the custom of eating cooked and overcooked food by the consumption of fresh fruit. In this country, more fresh fruit is eaten than in Europe, but there is room for a greater advance in this direction. As said before, conditions such as climate, occupation, and the personal equation must all be taken into account when dealing with the diet question, but it is an axiom that in all climates and in all occupations some fresh fruit should be eaten. Experience backed by scientific investigation has proved this to be true.

INFANT MORTALITY AND ITS CAUSES

It is beginning to be better understood that the majority of diseases which afflict civilized people are preventable. But treatment, or rather preventive measures, must be started very early in life. The most important and earliest measure is that the mother may be able to feed her own child herself and should not resort to artificial methods, however good these may be said to be. In all civilized countries the birth rate is falling.

France has the lowest birth rate and the birth rate of Great Britain is falling steadily. The birth rate of native born Americans, that is, of Americans whose forebears came to the country generations ago, is small, and while the quality may be good, they will be swamped by the numerous progeny of prolific immigrants, if the relative birth rate of the native born and newcomers continues in the same ratio.

One remedy is to save the infants born to Americans by inducing the mothers or rendering the mothers able to feed their offspring in the manner

that nature intended. At the present time, Great Britain presents, perhaps, the best example of a civilized industrial nation of which the birth rate is low and the mortality of infants is higher by far than it ought to be. Also in Great Britain preventive medicine is being practised on a wider scale than in any country. Sir Bruce Bruce-Porter wrote on the subject of infant mortality and its causes in the *Observer,* June 10th last, and pointed out that as the birth rate only slightly exceeded the death rate, no child should be allowed to die from preventable causes. It has been estimated that eighty per cent. of the children born are born free from actual disease, but in spite of this fact figures from the Health Ministry's own publications state that over sixty-one thousand babies died in the United Kingdom in 1918 before their first birthday and over ninety-three thousand died before the age of five.

Another statement emanating from the mouthpiece of the Ministry, Sir George Newman, is even more startling in its sinister significance. This is his estimate that in 1917 one million children were so mentally or physically defective as to be unable to derive reasonable benefits from the education provided for them by the ratepayers. Of course, a good deal of this physical and some of this mental incompetence can be prevented as they fall into these conditions through ignorance on the part of the parents. Therefore money spent on improving the health of the infant, and in preventing disease from developing, would be money saved over and over again at a later stage of this child's life. A child crippled in mind or body is a burden on the community instead of an asset, and as good health means prosperity, effective prevention of disease is an economical measure of the first importance.

A man is either independent and valuable to the nation or a parasite, existing on the work of others, and this statement applies to woman but to a less extent. Moreover, not only is a great deal of valuable time lost through preventable ill health, but half the people of Great Britain die before fifty.

On successful mothercraft depends the production of the sane mind in the healthy body. That is, the mother must be taught to care for her health and instructed how to do this properly. She ought to be able to nourish her child, and generally speaking will be able to do so if she knows how to care for herself during the child's prenatal stage and puts her knowledge into practice. Also, as a rule, the parent must be specially trained to care for the young and should not rely on what is known as "instinct." Early diagnosis is important in childhood, as heart disease for instance from rheumatic fever due to septic foci can be prevented by doing away with the cause.

Dr. Harry Campbell has pointed out many times that after weaning a child should be encouraged to eat and masticate thoroughly hard foods and not be fed on a pappy soft diet when it has its teeth. Too much sugar should be tabooed, as the eating of candy in large quantities is responsible for the early decay of the teeth, for oral sepsis and for disorders of the gastrointestinal tract. The young mother should know something of food values, and should not neglect to give children foods containing a sufficiency of vitamine content. Prenatal care is as essential as postnatal care. If the expectant mother does not care for herself she will produce an ill nourished infant which she cannot feed, and it must be borne in mind that healthy mother's milk contains elements combined in such a way that it cannot be successfully simulated by artificial feeding. An infant fed on its mother's milk starts life with a great advantage. After weaning it is improper food given in too large quantities, at too frequent intervals, that does the harm. The child, like the man, can dig its grave with its teeth and is often encouraged to overeat by injudicious parents. Unlike the man the child is not responsible for its dietetic errors or deficiencies, but its careless or ignorant parents must bear the blame.

IN SUPPORT OF THE NIGHTCAP

The medical profession have always been apt to contract obsessions. A leader of medicine will advocate a certain mode of treatment and the rank and file will frequently follow without a sufficiently due consideration of the circumstances of the case. In scientific diet for some time calories held sway and one's diet was largely ruled by its caloric content. Then it was pointed out that this was not really as it should be and that there was an elusive element of the diet which, although it had never been isolated, was essential to health. The overpowering consequences of vitamines in diet have been so persistently urged that at the present time the man in the street can converse glibly regarding the necessity for ingesting the various vitamines in adequate amounts and in correct proportions. Now, the vitamines are falling into the background somewhat, not that their value is minimized, and the need of the mineral salts in a diet is insisted upon as a primary condition of good health. And so it goes. Several years have passed since the supreme virtues of fresh air, especially in the treatment of respiratory affections, were lauded to the skies in all parts of the civilized world. A cult of fresh air was founded and its professors went to extreme lengths.

Consumptives in sanatoriums spent the day and frequently the night in the open air, as it was held that if they were well covered and their feet were

kept warm that they derived much benefit from this Spartan treatment. It was thought to be the height of effeminacy to sleep in a room in which the windows were closed, and, in fact, the cult of fresh air became an obsession. At first, no doubt, free ventilation came as a healthy reaction from the often stuffy sitting rooms of our ancestors, but the cult was carried too far and there are signs of reaction against the worship of the God of the Winds. In the first place, it has been shown that the evils of vitiated air have been considerably exaggerated, and that while what is termed pure air is more refreshing than a fuzzy atmosphere, that it is really movement in the air that is required.

Not long ago a late surgeon colonel, by name Beevor, of the British Army took his courage in his hands and recommended a return to the extinct nightcap. He propounds the thesis that the modern cult of fresh air has become a fanaticism and that to keep the body warm with quilt and hot water bottle, leaving head and neck icy cold, is to defy the rule of reason. He points out that socalled cold in the head and chill on the liver are the most generally recognized effects of interference with the normal working of the vasomotor nerves. Moreover, he does not agree that all colds in the head are due to infection, and considers that this theory has contributed to a dangerous belief in the benefits of pure air under any conditions.

Air needs to be of a temperature which will not interfere with the normal powers of the vasomotor nerves. Also, during sleep our vitality is at the lowest and he wishes to draw attention to the error of their ways of those well meaning but misguided people who pride themselves upon being fresh air fiends and sleep with a cold current of air in their bedrooms, even take their meals under similar conditions, and hopes to dissuade from adhesion to the fallacy that cold fresh air is a panacea for all catarrhal diseases.

Beevor largely bases his views on his experience as a medical man in the army, in which capacity he has been frequently and specially impressed by the baneful effects of a compulsory adoption of the fresh air cult carried to the extreme by soldiers on active service. He found that in the northwest frontier of India in regions in which the white man had never trod, where the air was pure as crystal, and the ground on which they rested was virgin rock, that colds among the soldiers were common. Almost similar phenomena were observed in the desert of the Upper Nile and of the Eastern Soudan, and these experiences shook his faith somewhat severely in the constant infectivity of colds and of the efficacy of preventive treatment by a copious and continuous supply of fresh air, however chilly it might be. For these reasons he thinks that our forbears had a certain degree of scientific sense in the adoption of the nightcap, and that it only required common sense to decide when to use it and when not.

It is an axiom, or should be, that a custom which endured for generations possesses some accruing advantage. The nightcap was worn throughout Europe for centuries. Chaucer referred to it in *Merchant's Tale* five hundred years ago. Possibly Mr. Pickwick's nightcap in that famous episode at the Great White Horse at Ipswich was the last time that style of headgear was mentioned in literature. Soon after that famous misadventure the nightcap went out of fashion, and doubtless Beevor's plea for its restoration in certain circumstances will have no more effect than that of Macaulay in Mid-Victorian times. Its day had passed and it had become an object of jest. Attention may be directed to one point, namely, that when nightcaps were common bedrooms were not scientifically heated and the four-post bedsteads with curtains and nightcaps for the occupants were more needed in the chillier and draughtier rooms of our forbears. But in the light of modern medical science there is sound reasoning in the argument of the British army surgeon that there are times when nightcaps may play an effective rôle in the prevention of disease.

MAIL FRAUDS

What affects one's purse is considered of vital moment compared with influences derogatory to life and health. This is well illustrated in the origins of war, for in modern national murder, at least, the chief exciting causes are commercial interests and the lives and health of thousands are sacrificed without mercy upon the altar of the money god. In the middle ages wars were waged more openly for commercial ends and they were more humane. The weapons were less deadly, and the prisoners were held at ransom (by which the victor made his money) according to rank and title. The rich man suffered according to his riches.

Our laws in regard to use of the mails may seem a long way from wars, ransoms and the like; nevertheless, a man may not, with impunity, use, in certain ways, the postal machinery to filch from his fellows their hardearned cash, but he can use it to hazard their life and health. The advertisements of cures, drugful or drugless, have free access to the mailbags and may menace health with slight concern on the part of anyone.

Books are denied access to the mails when they are supposed to corrupt the moral nature, but if they threaten indirectly the life and health of the reader, it seems of small matter. Our attention has been

called to a publication which, so far as we know, has the freedom of the mails. It is a socalled health book for laymen and the title is *Health via Nature*. So far as this title is concerned, there certainly is nothing to be complained of. In fact, we are unaware that health came by any other means. But the book is not devoted so much to health as to the cure of disease "by natural methods." Among these natural methods are high and low enemas, electric cabinets, etc. For sunstroke one should "dilute" the rectum. Harmless enough, this latter, but hardly "natural." But in diphtheria the recommendation is: "to loosen the false membrane and to get it to slough away, have the patient inhale steam through the nozzle of a teakettle." Of course there is no mention of antitoxin (save to decry the use of all serums), for "errors in eating and drinking no doubt are the source of diphtheria." Consumption is caused by "too rich diet," and the author is consistent in having the patient use milk, cream, butter, and eggs sparingly. "All milk should be diluted, half milk and half water." The patient must also avoid too starchy and too sweet foods, but as he must live chiefly on "fruits and whole grains" he will be in somewhat of a dietary dilemma.

Yet all this stuff can travel in the twentieth century as parcel post mail wherever it will in these enlightened United States.

THE PROGNOSIS OF APHASIA

It is hardly necessary to say that the prognosis in a case of aphasia in the first place depends upon the causal disease, but this is not the only factor to be taken into account. Moreover, great importance is to be attributed to the variety of aphasia. When it is motor in type, it has a greater tendency to retrogress than when it is of the sensory type. And nevertheless, in the initial phase, the aspect of a major anarthria appears much more alarming than that of an aphasia of the Wernicke type, because in the first type the patient remains conscious, while the subject afflicted by the second type does not appear to possess sufficient mental vigor to be reeducated. The extent of the lesions is important, although extensive destruction of the speech area may only be accompanied by minor disturbances.

The age of the patient is an element of prognosis to be most attentively considered. Aphasia in childhood is rare, and then only met with in subjects of eight or ten years, the process progressing rapidly toward a favorable outcome. In adolescents—in whom arterial lesions do not exist as a general rule —the aphasia retrocedes easily, without leaving any trace behind. In adults the lesions of syphilitic arteritis are apt to be the causal factor and with a properly applied antisyphilitic treatment the situation may be greatly ameliorated. In elderly subjects the prognosis unquestionably is gloomy, because even a mild aphasia is frequently accompanied by a marked intellectual deficit. The lesions of senile arteriosclerosis have no tendency to spontaneous repair and frequently an aphasia, which at the onset was mild, progressively proceeds to dementia, with all its unfortunate complications.

All things considered, the notion of the state of the intellect has become capital in importance at the present time in respect to the prognosis of aphasia. In point of fact, it is with what remains of the intellect and by a constant effort of the will that the patient may little by little recuperate a propor functioning of the automatism of speech.

Obituary.

SIR G. ANDERSON CRITCHETT

London

Sir George Anderson Critchett, Bart., K.C.V.O., surgeon oculist in ordinary to the King, passed away on February 9th, in a nursing home in London. It frequently happens that to be the son of a distinguished father is a serious handicap. Sir Anderson Critchett's father was perhaps the best known British ophthalmologist of the day, but this fact only acted as a spur to the son. He became perhaps the leader of ophthalmic surgery owing to his great skill as an operator and to his dominating personality. Indeed, his manipulative skill in eye surgery was a byword in the profession and he won the admiration of men whose own achievements in the same field made them peculiarly well qualified to judge. Especially he was regarded as one of the finest operators who ever dealt with cataract. In this connection it may be mentioned that writing on this subject in his *Archives of Ophthalmology,* Knapp, of New York, declared that in his opinion Critchett's method of operating for this condition eclipsed all others. It has been generally adopted by ophthalmic surgeons throughout the world.

Sir Anderson was seventy-nine when he died. He was ill for less than a week and almost to the end he was working with all the keenness that characterized his prime. He received part of his medical education at Caius College, Cambridge, and part at Middlesex Hospital, London, and in Paris and Germany, qualifying in 1872. Much of his work was done at St. Mary's Hospital, to which he became consulting ophthalmic surgeon. Up to 1881 he was attached to Moorfields, the special eye hospital of London, and to the Royal Free Hospitals. He was senior ophthalmic surgeon to King George's Hospital. In 1901 he was appointed surgeon oculist to the late King Edward, and in 1910 surgeon oculist to King George, becoming surgeon oculist in ordinary to the King in 1918. The honor of Knighthood was conferred upon him in 1901, he was made a baronet in 1908, and K.C.V.O. in 1919.

News Items.

Harvey Society Lecture.—Dr. Wilhelm Kolle, professor of medicine, University of Frankfurt am Main and director of the State Institute of Experimental Therapeutics, will deliver the eighth Harvey Society Lecture at the New York Academy of Medicine on Saturday evening, April 18, 1925. His subject will be "The Abortive Cure of Syphilis in the Light of Experimental Studies."

Memorial to Doctor Berens.—In memory of Dr. T. Passmore Berens, for thirty-three years connected with the Manhattan Eye, Ear and Throat Hospital, a tablet has been erected at the hospital.

Lectures at Columbia.—The Columbia University School of Medicine has decided that clinical lectures of the third and fourth year will hereafter be open to the general medical profession.

Honorary Degrees from Dublin University.—Dr. Charles H. Mayo, of Rochester, Minnesota, and Dr. George W. Crile, of Cleveland, Ohio, have received the honorary degree of master of surgery from Dublin University, Dublin, Ireland.

Postgraduate Courses.—The University of Pittsburgh Medical School announces a two weeks postgraduate course for the general practitioner, and a third week of laboratory instruction if desired, to begin June first. The cardiovascular system will be dealt with in particular.

"Hospital on Wheels."—A bill has been proposed in the Illinois legislature for a railway coach to be fitted with modern hospital conveniences and to provide quarters for disaster relief workers. The coach would be kept in Springfield, which would enable it to reach any point in the State in six hours. An appropriation of $60,000 is requested.

Health Institute at Portland, Maine.—The New England Health Institute will be held in Portland, Maine, from May 4th to 9th, under the auspices of the U. S. Public Health Service, the New England State Health Departments, Yale, Harvard, Massachusetts Institute of Technology, and Simmons College. The only expense is a registration fee of one dollar.

International Health Delegates.—A group of delegates from Latin American countries, under the International Interchange of Health Officials, part of the activities of the League of Nations, are in this country, their itinerary being arranged by the Surgeon General of the Public Health Service. The date of the arrival in Washington is April 6th, and Baltimore and New York will be visited.

French Tuberculosis Study.—The *Association Alsacienne et Lorraine Contre la Tuberculose* announces a postgraduate course in the study of tuberculosis, to be given by the faculty of Medicine of Strasbourg, from October 9th to 24th, at the University. The fee is two hundred francs. Information may be obtained from Dr. Vaucher, rue de l'Université et 8, quai Finkwiller, Strasbourg, 22, France.

Papers on Neurology.—The Section of Neurology and Psychiatry of the New York Academy has arranged the program for the stated meeting, April 16th. The following papers are to be presented: "Ultimate Cause of Most Hemiplegias" by Dr. Thomas F. Reilly; "The Proper Classification of the Cerebral Palsies of Early Life," by Bernard Sachs; and "Static and Kinetic Representations of the Efferent Nervous System in the Psychic Sphere," by Dr. J. Ramsay Hunt.

Civil Service Examinations.—The U. S. Civil Service Commission, Washington, D. C., announces examinations for junior medical officer, assistant medical officer, associate medical officer, medical officer, and senior medical officer, for vacancies in various branches of the Government service, at entrance salaries from $1,860 to $5,200. Applications should be received before June 30th; competitors will not be required to report for examination at any place, but will be rated on education, training, and experience.

Examinations for entrance into the regular corps of the U. S. Public Health Service will be held June first at Washington, Chicago, New Orleans, and San Francisco. Applicants must be between twenty-three and thirty-three years of age, graduates of medicine with one year's hospital or two years' professional experience. Oral, written, and clinical tests and a physical examination will be required. Applications should be addressed to the Surgeon General, U. S. Public Health Service, Washington, D. C.

Benefit for Physicians' Home.—The Century Theatre, where "The Love Song," with music from Offenbach, is being given, has been secured for a benefit performance for the Physicians' Home, on the night of Monday, April 20th. Physicians purchasing two or more tickets for box seats, orchestra, or dress circle, will receive membership certificates for 1925. The Physicians' Home is an organization for help to physicians who through age or illness, need assistance. Tickets may be obtained by mail from the secretary, Dr. Silas F. Hallock, 901 Lexington Avenue, New York.

Montefiore Hospital Anniversary.—Montefiore Hospital for Chronic Diseases, New York, held its fortieth anniversary on April 5th. Dr. George E. Vincent of the Rockefeller Foundation gave an address on "The Hospital and the Community," and S. G. Rosenbaum, president, read a report tracing the history of the hospital, planned in 1884, in commemoration of Sir Moses Montefiore who was then alive, and celebrating his hundredth birthday. A tribute was paid to the late Jacob H. Schiff, who was on the first board of trustees, and who was president for thirty-five years. The first building of the hospital was at Eighty-fourth Street and Avenue A, where a building with space for twenty-six beds was leased for thirty dollars a month.

Personal.—Dr. Ernst P. Boas of New York spoke on "The Clinical Significance of Recent Studies of the Capillaries" before the Buffalo Academy of Medicine, April 8th.

Dr. Wade H. Brown of the Rockefeller Foundation recently lectured on "Chemotherapy and Treatment of Syphilis," at the University of Michigan.

Dr. Frederic W. Bancroft of New York has been appointed surgical director of the Lincoln Hospital and Home.

Dr. Fred H. Albee of New York gave an address and held an operative clinic before the Fulton County Medical Society, of Atlanta, Georgia, on the occasion of the opening of the Atlanta Graduate School of Physicians and Surgeons.

Dr. Philip Horowitz of New York spoke before the Dauphin County Medical Society, Harrisburg, Pennsylvania, on "Present Concept of the Use of Insulin in the Treatment of Diabetes."

Postgraduate Clinic Tour.—The Interstate Postgraduate Assembly, directed by the Tristate District Medical Association, announces that there are still some vacancies for physicians desiring to take advantage of its foreign tour. This tour includes clinics in Toronto and Montreal in this country, leaving Montreal May 23d, and clinics will be held in Liverpool, Manchester, Leeds, Dublin, Belfast, Glasgow, Edinburgh, Newcastle-upon-Tyne, and Paris. Dr. Charles H. Mayo will be presiding officer of the tour, and Dr. William B. Peck, of Freeport, Illinois, managing director. Clinic space has been planned to accommodate five hundred physicians, and two one cabin ships have been chartered for passage. The trip can be arranged at less than one thousand dollars. Reservations accompanied by a fee of sixty-five dollars to hold space should be sent to Dr. Peck.

Opportunities for Graduate Medical Study in New York.—The Committee on Medical Education of The New York Academy of Medicine has prepared a series of synopses of approved opportunities for graduate medical study in New York City which will soon be published for distribution. The synopses cover dermatology and syphilology, obstetrics and gynecology, internal medicine, neurology and psychiatry, ophthalmology, otolaryngology, pediatrics, surgery, urology, and orthopedic surgery.

A Bureau of Clinical Information is maintained at the Academy of Medicine, 17 West Forty-third Street, where detailed information is available regarding, opportunities for graduate medical study in New York, and also in other cities of the United States and abroad. The executive secretary in charge of the Bureau is prepared to answer inquiries concerning ordinary internships, special internships or residencies, graduate courses in medical schools and teaching hospitals, and extension courses. Much information in regard to graduate medical work in England and on the Continent is on file.

The bureau publishes a *Daily Bulletin of Surgical Clinics* which will be mailed free to visiting doctors on request. *A Weekly Bulletin of Medical Clinics* also is published. A book of the fixed clinics of Greater New York, with a transportation guide, has been prepared for the use of visitors whose stay in the city is limited, and is furnished without charge.

London, *March 7, 1925.*

EPSOM COLLEGE WAR MEMORIAL

Epsom College is an educational institution founded in 1855 by Dr. John Propert with the intention of constituting a foundation for fifty boys, the children of medical men, where circumstances had precluded the boys from the opportunities usually enjoyed by the sons of the professional classes. Briefly stated the Royal Medical Foundation of Epsom College exists, first, to give pensions to fifty aged or disabled medical men or their widows, and, second, to provide, free of charge, a good public school education, together with clothing, maintenance and pocketmoney, to fifty sons of deceased or disabled medical men. Last year, generous benefactions had so increased the value of many pensions that the college bestowed no fewer than one hundred and sixty-six pensions. However, it is the educational work which arouses the widest and warmest sympathy. There is keen competition for the fifty foundation scholarships, which have given chances in life to many poor boys who otherwise would have lacked the advantage of a first class education. Over and above these fifty foundation scholarships, the college offers privileges to the sons of medical men who are provided with a public school education at as near cost price as possible. While Epsom College has developed into a first class public school, second to none in this country, it should not be forgotten that the prime reason for its foundation was to benefit medical men and their families and it may be added that it has fulfilled this, the true object of its founders, in the most highly satisfactory way.

Among the early benefactors of the college were the proprietors of the *Lancet,* who when the scheme was mooted sent £1,000. Epsom College has prospered exceedingly, and in the great war one thousand of its old boys joined the colors, of whom one hundred and forty gave up their lives. In memory of these brave men the chapel has been added to, in fact, transformed at the cost of £11,500. Towards this memorial fund Lord Rosebery, president of the college, has given £1,000, and the other subscribers have been mainly the relatives of the fallen, and old boys and parents of boys now in the school. On Saturday, February 21st, amid impressive ceremonial and in the presence of a distinguished congregation, the Bishop of Winchester consecrated the reconstructed Epsom College Chapel. It should be explained that a public school here does not mean the same as in America. In this country the public schools are for the education of the prosperous and professional classes.

SIR CLIFFORD ALLBUTT

Although Sir Clifford Allbutt, regius professor of physics in the University of Cambridge, had reached a green old age, his mental faculties were so alert that no one regarded him as an old man. Only three days before he passed away the *Lancet* received from him a letter, published in its issue of February 28th, which showed that his mind was as agile and his reasoning power as logical as ever. A friend of the writer also had a letter from him written at about the same time promising his support of a candidate for a foundation scholarship at Epsom College.

Sir Clifford Allbutt was the acknowledged leader of the British medical profession and was chiefly distinguished by his unrivalled clinical experience and acumen, by the remarkable literary powers, and by the successful manner in which he dealt with men and things. He was a scholar, a literary man and a great physician, and at the same time eminently practical. He shone in whatever branch of medical science he took up. For instance, he was a conspicuous success as a Commissioner of Lunacy. No doubt, however, the Regius Professorship of Physic in Cambridge University was exactly suited to his genius and bent of mind.

While he was fifty years of age at the time of his appointment, he quickly adapted himself to the academic life. He was an extraordinarily versatile man, a good classical scholar and as said before a writer of rare distinction. When in Leeds he lived not far from the dwelling place of that tragic family of geniuses, the Brontes, with whom he was connected by family ties. The Miss Wooler to whose school Charlotte Brönte went, and in whose school Charlotte Brönte taught for a time, was related to Sir Clifford Allbutt. Charlotte Brönte and Sir Clifford were friends and when she, the last and greatest of that ill fated family of conspicuous abilities, died, she left the manuscript of some of her books to Sir Clifford, who placed them in the Fitzwilliam Museum in Cambridge. He also knew well George Eliot and other giants of literature of the Victorian era. We shall never look upon his like again, at once highly cultured, deeply scientific and above all practical in that he was strongly conscious of the immense value of clinical experience. In appearance he resembled that prince of diplomats, the Earl of Dufferin, and courtly in manner, almost exuded graciousness and kindness.

Sir Clifford was liked and respected by all with whom he came into contact and loved by his friends.

DEATH OF DR. GEORGE SIGERSON

At a ripe old age a celebrated scientific medical man and a man of varied literary interests died in Dublin on February 17th, last, in the person of Dr. George Sigerson. He was a pioneer in Ireland in the modern treatment of nervous diseases. He had been a pupil of Charcot.

Dr. Sigerson was as well known in politics as in medicine and was the writer of an article which appeared in one of the leading nationalist journals of the time of which the notorious Pigott, the author of the forgery in the *Times* with reference to Parnell, was the editor. Pigott was sentenced to twelve months' imprisonment for publishing the article and afterwards comitted suicide when his forgeries in the Parnell case were discovered. Sigerson was a man of wide learning but essentially a student and although he took a somewhat prominent part in the nationalistic affair of Ireland was what used to be called in Germany "a revolutionary of the chair." He was not known to the man in the street. He was an idealist, almost a visionary, and on account of his

indifference to the material side of life, it occurred that the possessor of the most brilliant and best equipped medical mind in Dublin was a failure from the worldly point of view. Sigerson's knowledge was remarkable. He spoke French as a Frenchman and he knew German, and was one of the few men who really knew the language, the literature and the history of his own country. He was a journalist of the most brilliant type, he wrote concerning the results of microscopic investigations, of heat as a factor in vital action of the buoyancy of bodies of greater density than water, of flowers and advances in botany.

He translated Charcot on the nerves and wrote on paralysis and the geographical changes in the soil of Ireland. Perhaps, however, the best work that Sigerson did were his books on Irish history and literature. Sigerson was a professor of biology and a practising physician but was an academician who lived an isolated life and appeared to regard the tremendous happenings of his day somewhat with the ironic and detached air of a scientific onlooker. His writings on political questions show that he took a keen interest in them, and it is likely that under an impassive and reserved manner he concealed the strongest feelings that his seeming detachment was due to the fact that he knew that the majority of those who read the writings did not understand them. It was an intellectual superiority which cannot but breed a certain amount of contempt for those lacking in knowledge. Dora Sigerson, who inherited her father's mysticism, was a well known writer of poetry. She married Clement Shorten, the famous English journalist, and died in 1915.

DISEASES OF THE CLIMACTERIC IN BOTH SEXES

At a meeting of the Chelsea Clinical Society, held at St. George's Hospital on February 17th, Sir Thomas Parkinson opened a discussion on diseases of the climacteric in both sexes. He drew attention to the changes that accompanied this period of life in men. Many men at this time of life showed changes in arterial tension with or without renal changes. He pointed out the uselessness of attempting to reduce the blood pressure in these cases by means of drugs and said that alteration in the surroundings of the man, with lessened diet and rest in bed were the chief assets in securing relief. In the female the flushings experienced at the climacteric were, he thought, due to the loss of ovarian secretion, and this loss upset the action of the thyroid and adrenals. At this period of life in both sexes the endocrine organs were very erratic. He considered the upset of the normal mental condition was due in many cases to the thyroid. The cause of the excessive headaches was possibly due to affections of the pituitary gland. It was important that men should be treated before definite changes had been established in the vascular system. He thought that people of both sexes ate far too much at all times, and that such excess was most harmful at this period of life.

Mr. A. Ralph Thomson put the age of the climacteric as from about fifty-five to sixty-three years in the male. He showed that sepsis was more common in the male sex than in the female at about this time of life, and that the chief septic changes were associated with gangrenous or necrotic processes. Mr. Thomson commented on certain clinical facts he had observed in connection with cancer of different parts of the body. He had noted the curious absence of bloom from the complexion of the face in cases of malignant disease, which he compared with the absence of bloom observed on the leaves of plants grown under calcium free conditions. In his experience the thyroid was enlarged in not a few cases. Some of the thyroids in malignant disease that had come under his view were very large. Acting on these observations he had been used to prescribe calcium and thyroid, and he gave an interesting account of some cases of inoperable carcinoma of the bladder, in which some improvement had been seen after this treatment.

Dr. Theodore Hyslop pointed out that many men exhibited psychical symptoms at about the age of fifty, and he thought that this was associated with the periodical holding up of uric acid in the system. He advocated saline purges for this condition with diaphoresis.

LATIN AMERICA LETTER

(From our own correspondent)

BALBOA HEIGHTS, C. Z., *March 10, 1925.*

PHYSICIAN INTERCEDES IN INDIAN UPRISING

Dr. John G. South, formerly of the State Board of Health of Kentucky and at present Minister to Panama from the United States, is now in the San Blas Country of Panama conferring with the Indian chiefs of the San Blas tribes relative to their recent uprising against the Panama Government. Several weeks ago there was reported a serious massacre of the Panama garrison of military police stationed on the Islands. During the fighting there were twelve Indians and twenty-two Panamanians killed. Upon receipt of the report the Government of Panama sent a detachment of troops to the aid of the rest of the garrison and at the same time Doctor South sailed for the scene of hostilities on the U. S. cruiser *Cleveland*.

Following a lengthy interview with the San Blas chieftains at Carti, the Indians promised Doctor South that they would stop hostilities provided the Panama forces would not attack them. It is reported that the massacre was incited by a proclamation of independence promulgated by an American, R. O. Marsh, the discoverer of alleged white Indians in that country.

An editorial comment of the *Star and Herald* of Panama makes the following statement: "If it were not for the tragic consequences, the 'San Blas declaration of independence' as composed by 'explorer' Marsh would be almost sufficiently amusing to compensate one for wading through its great length. It is to be regretted that this trouble could not have been anticipated and the cause for grievances of the San Blas Indians investigated and removed as nearly as possible in the circumstances, and to that extent there is the responsibility for furnishing the powder, but the responsibility for touching it off would appear to rest with R. O. Marsh, judging entirely from the document that bears his initials."

It will be remembered that there was reported

previously in these columns the "discovery" of white Indians by R. O. Marsh, who took four of these to the United States in an endeavor to prove his claim. Marsh, it is reported, is at present on board the *Cleveland* under the protection of the American minister.

The San Blas Indians are usually peaceable by nature and have been in communication with civilization for some time. They have, however, one peculiar superstition persisting. No white man is allowed to stay on their island over night, for to do so would produce a spell of the evil spirit upon them. Hence all white people visiting the islands must at nightfall return to their vessels.

FURTHER STUDY OF SAN BLAS SOCALLED WHITE INDIANS

Dr. R. G. Harris, director of the Biological Laboratory of the Long Island Biological Association, has just returned from San Blas Islands, where he has been carrying on intensive studies of the socalled white Indians inhabiting these islands. In discussing his studies, Dr. Harris pointed out that true albinos whether in men or animals, have pure white hair and pink eyes. But the blond Indians of San Blas have hazel eyes and flaxen or auburn hair. The blond Indians form a greater proportion of the population of the region than albinos which are known in other regions of the world. Dr. Harris has collected data which he thinks will show conclusively that this partial albinism is inherited and that it runs in families and whereas there is not yet a race of white Indians, the present partial albinos hold potentialities which under favorable conditions may be turned to race production.

Previous to his visit to San Blas Dr. Harris made a large collection of tropical insects of Panama for the museum of the Biological Laboratory and also carried on investigations on the caterpillar of the moth hawk, the most destructive insect in this section.

NATIONAL MEDICAL CONGRESS OF CUBA

During the year 1924, Havana, Cuba, has been the seat of not a few scientific congresses. The two most notable of the year were the Pan American Sanitary Congress and the Cuban National Medical Congress. Both of these were well attended by many notables from the United States. Over one thousand persons attended this last congress and among the most noted were Doctors Gant and Fox and Andrews. Dr. F. M. Fernadez, the Secretary-General of the present congress was elected president for the ensuing year. Many features of importance to Cuba were taken up at the meetings, including resolutions recommending legislation for the proper control of immigration, improved food and drug control and the inauguration of a Health Officer's Training School. There were also passed resolutions for the establishment of laws for the protection of the public against quackery and nostroms.

PUBLIC HEALTH CONGRESS OF BRAZIL

The second Public Health Congress of Brazil was held during the month of December, 1924. Many subjects of vital importance to that Republic were discussed. Among them the most important was, epidemiology, rural sanitation, with reference to the control of hookworm and malaria with the eradication of this latter disease through anti-malarial sanitary work. Attention was also called to the very meagre reports on vital statistics from the rural districts and the great need for the establishment of a more improved system of collection.

Interest was displayed in the section of child hygiene. It appears that more thought is being given to this important subject by the Public Health Officials of South America in general. Many papers were read on school hygiene and the establishments of proper standards for this work. The substitution for theoretical teaching of hygiene by practical methods was discussed at great length. Suggestion was made of the addition of a school hygiene department to the National Public Health Service.

HEALTH CENTRES OF THE ZONE REOPEN

The Health Department of the Canal Zone announces the reopening of health centres in Ancon and Balboa for the benefit of the children living on the Pacific side. These will be open twice a week and in charge of a physician and a public health nurse. Stress is laid upon the fact that while these are for the benefit of children of all ages mothers are particularly requested to bring their infants and children of the preschool age. It is the desire of the health department to secure accurate records of all the children of the Zone with the view of improving their health so that when they enter school they will be as free as possible from remediable defects and in a condition to meet the new environment with the least impairment to their physical condition. Dr. George Eugene, of Ancon Hospital, and Miss Katterine Luby, the Public Health nurse, will have charge of the centres.

AN UNUSUAL ACCIDENT

Of great medical interest is the unusual accident that befell a sailor of the S.S. *Swiftscout,* which transited the Canal a few months ago. Falling overboard from the ship at sea, bitten through the left leg by a shark, and fighting his way through a rough sea and a treacherous current off the Island of Taboguilla and remaining on the island for three days without food, is the harrowing experience of George Wickey, chief cook of the ship.

It appears that after shore leave Wickey returned to his ship at the Balboa docks at midnight and then went to sleep on the poop deck. The ship put to sea without his awakening and the next thing he knew he was in the water struggling and calling for help as the ship passed out of sight. On his right he could make out a light and toward this he started to swim. In a few moments he was grabbed by some monster of the deep, possibly a shark, which inflicted deep lacerations in his left leg. In his struggles he managed to kick, which broke the hold of the fish. It then disappeared and did not attack him again. He continued to swim, although in great pain from his wounds, and after a battle with the waves for three hours landed in an exhausted condition on the rocky shore of Taboguilla. While swimming he divested himself of all clothing except his singlet. Tearing the hem off this he tied it around his leg to stop the flow of blood. After being cast up on the shore, and just as dawn was breaking, he fell asleep. Here for three days without food or cloth-

ing he braved the elements. This island is uninhabited and he was rescued by fishermen who brought him to the Canal Zone, where he was taken to Ancon Hospital for treatment. The man was suffering intensely from infection of the wounds and from severe sunburn when he arrived at the hospital. During his stay double pneumonia and pleurisy developed. The bites from the fish severed some of the nerves. The man is still in the hospital making slow convalescence.

SANITARY TREATY BETWEEN COUNTRIES OF SOUTH AMERICA AND UNITED STATES APPROVED

Word has been received that the Foreign Relations Committee of the U. S. Senate has approved the conventions between the countries of South America and the United States providing for uniform regulations governing ports and shipping to prevent the spread of disease. The conventions of the treaty are in the main the result of the different resolutions adopted at the various Pan-American Sanitary conferences throughout a number of years. The culmination of these took place at the Seventh Pan-American Sanitary Conference held at Havana, Cuba, last November. The authority under which the Sanitary Code was drafted is as follows:

WHEREAS, The various international conferences of American States have adopted recommendations or resolutions relative to: a, The general welfare of the Republics of America; b, Sanitary policy and the means of preventing the introduction and propagation of communicable disease; and c, The means of promoting international commerce; and

WHEREAS, The various international sanitary conferences have adopted numerous resolutions and recommendations and have signed a convention for: a, Preventing the propagation and suppressing communicable diseases; b, Quarantine, fumigation, disinfection, and methods of inspection regarding vessels engaged in international commerce; and

WHEREAS, Modern quarantine methods and procedures have advanced to such a point that if uniform systems are employed a maximum of protection may be obtained, with a minimum of delay for commerce, therefore be it

RESOLVED, That the International Sanitary Office be entrusted with the preparation of a project of International Code of Maritime Law, which the Seventh International Sanitary Conference to be held at Havana at a date to be fixed during the year 1923 shall study, approve, and adopt in the form of a treaty.

For the United States, Surgeon General Hugh S. Cumming and Assistant Surgeon General John D. Long of the U. S. Public Health Service have been for the past few years industriously working upon the code and the approval of the conventions are in part due to their labors.

CANAL ZONE MEDICAL ASSOCIATION

The 218th meeting of the Isthmian Canal Zone Medical Association was held on Tuesday, February 17, 1925, at the Century Club in Panama. The association was the guest of the Herrick Clinic, which has a fine hospital and clinic in Panama City.

EXPLOSION AT BARBADOS RESULTS IN FOUR DEATHS

Information received on the Isthmus during the month conveys the sad intelligence of an explosion which occurred in the harbor of Barbados on a Canadian steamer, February 19th, when four laborers were killed outright and many injured. A fire broke out in hold No. 2 and gradually worked its way to a cargo of five hundred barrels of gasoline. Impossible to control the fire, she was towed to sea, where the ship was completely demolished.

NARCOTIC SMUGGLERS APPREHENDED

For the past few months unconfirmed reports have reached the health department of the smuggling of narcotics into the Canal Zone. Due to the activity of the Customs service, Manuel Beana, of Colombia, was recently apprehended, tried and sentenced to ten years in the penitentiary at Gamboa on the Zone. He was in addition fined $500. This is the maximum penalty for dope smuggling. It is thought that Beana is the ringleader of a gang.

QUARANTINE AGAINST BRITISH HONDURAS LIFTED

Owing to the fact that the Stanncreek District of British Honduras has been free from yellow fever for the past several months, Surgeon C. P. Knight, chief quarantine officer of the Panama Canal, has issued an order raising the quarantine on account of yellow fever against the ports of British Honduras.

Letters to the Editor.

DIATHERMY IN CARDIOVASCULAR DISEASE

NEW YORK, *March 23, 1925.*

To the Editor:

May I invite attention to an error of assumption in the otherwise excellent paper of Dr. Baruch Last on the Use of Diathermy in Cardiovascular Diseases, published in your issue of February 18, 1925?

In two places he speaks of the blood as being more heated than the rest of the tissues by diathermy and speaks of axillary temperature being higher than rectal in general diathermy as a proof. First, high potential currents pass through substances resistant to low voltage currents. Then Joule's law cannot be set aside even in living tissue. The heat generated is always proportional to the resistance of the circuit; hence bone will heat up more than muscle and muscle than blood. The heat generated is equal to the square of the amperage, double the amperage and you quadruple the heat, and the heat generated is proportional to the time of current flow.

If the two terminals of the d'Arsonval or Tesla coils be attached to electrodes on separate ankles, a thermometer in the rectum will show a decided rise in temperature. The same thing may be observed when the electrodes are placed on abdomen and sacrum.

The reason the blood is hot is because it is draining a heated area, just as water from a boiler is hot (it is conducted heat), and so it circulates giving off its heat by radiation through evaporation of perspiration and lung vapor and by conduction to other organs. If the blood did not circulate through the heated area the tissues would remain hot and be damaged. For this reason diathermy in scar and fibrotic tissue which has poor circulation that cannot be increased, and in anesthetic areas where reflex hyperemia cannot be excited, is to be used with extreme caution and in small doses. The greatest heat in Dr. Last's technic would be near the back. The relief of tension is evidently due to the relief of spasm of the vasa vasorum which may result from the same cause or the analgesia or may be due to the effects of heat.

FRANK THOMAS WOODBURY, M.D.

Book Reviews

MEDICAL EDUCATION

Medical Education. A Comparative Study by Abraham Flexner. New York: The Macmillan Company, 1925.

As indicated by the author in his preface, the volume under consideration is devoted to a comparative study of medical education—and, the reviewer may add, of preparatory training, both general and special—in certain European countries and America as influenced largely by the general educational and social systems of the respective countries. Flexner finds fault with the lack of thoroughness in much of the teaching in primary and secondary schools of this country. It is his opinion that "the best schools are somewhat superior in the cultural quality of their student body to the inferior schools; but even they fall below the European level. Those who question this opinion may satisfy themselves by comparing the current literature of medicine and surgery in various countries in respect to vigor of expression, background, range of acquaintance with medical history, and other criteria, calculated to disclose not only technical mastery but general training." To this dictum the reviewer begs, respectfully, to demur. It may apply to the average of our extremely large output of scientific literature; it most certainly does not apply, in his humble opinion, to the best done here compared to the best done abroad. But be that as it may, there is no question about the truth of Flexner's statements as to the defects of our educational system. For that reason, as well as for the exceedingly able presentation of a most important pedagogical study, his book will be read with interest as well as with profit by educators lay and medical.

THERAPEUTICS

A Textbook of Practical Therapeutics. By Hobart Amory Hare, M.D., LL.D. Nineteenth Edition. Philadelphia: Lea & Febiger, 1925.

The reviewer has long agreed with the author of this book on the importance of therapy. It is a major medical subject, and the object for which a patient comes to a physician. Therapy does not mean drugs only, but any method of treatment, including surgery, that will cure or help a patient.

This book aims to teach the subject of treatment broadly and to help the student and physician to think before he dogmatically uses a drug or physical treatment. The word empirical has been scoffed at and much misused, but when long and careful clinical observation has shown a drug or treatment to be of value in a certain condition, it becomes rational treatment, even if its exact action in the body is not known. Many empirically used drugs have become rational and even specific by later laboratory investigations; as instances, codliver oil, quinine, and mercury may be mentioned.

In the author's classification of drugs, page 55, he still perpetuates the heading of "alteratives," which could well be eliminated and the drugs classified by their actual uses or activities. The part of the book devoted to the alphabetical description of drugs is, as usual, well written and terse. The description of alcohol shows it is a drug of value in proper cases, and because it is under a ban as a beverage is no reason for abandoning it as a drug. The newer drugs have been added and their action described. Quite a number of the useless drugs might be eliminated, although the author aims to explain even ancient things. A few of those that might be eliminated are, agaricin, ammonium valerate, azederach, columba, camphoric acid, catechu, conium, Hoffmann's anodyne, Hope's camphor mixture, hypophosphites. Hypophosphites have no activity whatever. The value of preparations of them is in the other ingredients which such preparations contain.

The parts of the book devoted to remedial measures other than drugs and to foods and diets is excellent as usual.

Part IV, devoted to suggestions for the treatment of different diseased conditions, is arranged alphabetically, as is the rest of the book, and gives ready reference for authentic treatment of disease and diseased conditions. Two carefully prepared indices make the book valuable for cross references.

The type is just right, and the make up of the book splendid.

ALOPECIA

Sammlung zwangloser Abhandlungen aus dem Gebiete der Dermatologie und Syphilidologie. Mit besonderer Berücksichtigung der allgemeinärztlichen Praxis. Herausgegeben von Prof. Dr. J. Jadassohn, Breslau, und Prof. Dr. F. Pinkus, Berlin. III Band, Heft 1. Der Ausfall des Kopfhaars und seine Behandlung. Von Prof. Dr. med. Felix Pinkus, in Berlin. Neue Folge, Heft 5. Beziehungen der ekzematösen Erkrankungen zu inneren Leiden. Von Hofrat Prof. Dr. S. Ehrmann, Wien. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1924.

The monograph by Pinkus deals with the various types of alopecia and their treatment. After discussing the fetal growth of hair and its anomalies, the residual scalp hair and its disappearance, acute alopecia, mixed alopecia, chronic alopecia, sclerotic alopecia, and the length and pigmentation of hair, acute alopecia due to erysipelas, local depilation and syphilitic alopecia are discussed. Acute alopecia not due to inflammatory changes in the scalp (alopecia areata) is of two types: 1, the common variety of alopecia areata, and 2, the neurotic and endocrine forms of alopecia areata. The treatment recommended includes the use of humagsolan, a dialysate of a horny substance, internal remedies, such as arsenic and sulphur, and local treatment.

The monograph of Ehrmann is concerned with the relationship between eczematous diseases and internal diseases. Inasmuch as there is some confusion as to the exact definition of eczema, the author sharply defines the term. The relationship between eczema and the disturbances of metabolism, as it is encountered in diabetes, the uratic diathesis and in nephritis, is discussed. A certain type of eczema is seen to occur around the orifices of the digestive and urogenital tracts, as around the mouth and rectum. A description, the diagnosis, the etiology and the associated disturbances in the digestive tract and endocrine system, of neurodermitis are given. The general and local treatment of neurodermitis is given in detail.

MICROSCOPY OF THE LIVING EYE

Microscopie de L'Oeil Vivant. Par F. Ed. Koby. Paris: Masson et Cie., 1924. Pp. 240.

The introduction of the Gulstrand slit lamp (a modification of the Nernst lamp) marks a distinct achievement in the methods of eye illumination for examining purposes, and with the aid of the corneal microscope enables the examiner to obtain a most satisfactory view of the structure of the anterior portion of the eyeball. The illumination being very intense and concentrated, a high degree of magnification is obtainable, and minute study of the conjunctiva, cornea, iris, lens and vitreous is made possible.

This new field of microscopy of the living eye opens a wide vista of possibilities in the study of both the normal and the pathological eye, especially in the early recognition of certain conditions that escape the hitherto known methods of examination. It takes, however, a considerable degree of experience to manipulate the instrument, and still more to interpret the findings as they present themselves under this method of examination, and it is the purpose of this present work to assist the reader in acquiring this experience. With this in view the description of the apparatus, the technic of the examination, and the findings elucidated are gone into at considerable length and with painstaking details. While the work will stand no comparison with Vogt or Koeppe (in German) on the same subject, its conciseness and lucidity (we wish we could say the same of its few, too few, illustrations) recommend it as a serviceable guide book to the French reading ophthalmologist, who will, by the way, find in the author's bibliography of some eleven closely written pages everything of importance that has appeared in the literature of the last few years.

OVARIAN TUMORS

Würzburger Abhandlungen aus dem Gesamtgebiet der Medizin. Gegründet von Prof. Dr. Joh. Müller in Nürnberg und Prof. Dr. Otto Seifert in Würzburg. Neue Folge herausgegeben von Prof. Dr. E. Magnus-Alsleben in Würzburg. Zur Pathologie und Klinik der Ovarialtumoren. Von Dr. E. Stübler und Dr. Th. Brandess, Assistenärzte der Universitätsfrauenklinik in Tübingen. Neue Folge, Band I, Heft 9. Leipzig: Verlag von Curt Kabitzsch, 1924. Pp. 249-360.

Ovarian tumors, as well as other tumors, are neoplasms of an autonomical character. This definition excludes cysts. Tuboovarian cysts are therefore not included. Ovarian tumors are divided into epithelial, connective tissue, endothelial and mixed tumors. The lack of definite knowledge of the epithelial variety leaves the latter a still unsolved problem. Among the epithelial tumors, the ciliated epithelium cystomas and the pseudomucin cystomas must be differentiated.

Epithelial tumors may be divided into two groups: 1, mature forms, including simple serous cystoma, papillary serous cystadenoma, pseudomucinous cystadenoma and simple adenoma; 2, immature forms, which are again subdivided into, a, primary ovarian carcinoma, and b, metastatic ovarian carcinoma. The former includes adenomatous carcinoma, solid carcinoma, serous cystadenoma with malignant degeneration and pseudomucinous cystadenoma with malignant degeneration.

The connective tissue tumors of the ovary are also divided into 1, mature forms, such as fibroma and fibromyoma, and 2, the immature forms, including spindle cell sarcoma, round cell sarcoma, mixed sarcoma and endothelioma.

The mixed tumors include dermoid cystoma and struma of the ovary, malignant degeneration of dermoid cystoma and teratoblastoma.

The material collected for fifteen years includes 682 tumors in 670 patients. Ovarian tumors were found in 3.3 per cent. of 20,247 patients. The specimens were carefully studied microscopically and by several investigators to insure correct conclusions. The material was also worked up statistically in minute detail and a careful followup system was instituted. This monograph is probably the most complete work on the subject of ovarian tumors viewed from every angle.

CLINICAL DIAGNOSIS

Precis de Clinique Sémiologique; Diagnostics, Pronostics et Traitéments. By Gaston Lyon. Paris: Masson et Cie, 1924. Pp. 700.

It is an unfortunate, but nevertheless true, observation that more diagnoses are missed by the lack of application of available methods for revealing the presence of disease than by any abstract difficulty itself. Today, with our multifarious laboratory and physical methods for examination of the patient, there is much less excuse for errors in diagnosis than a decade ago, when many of the procedures which should now be in use by the practising physician were unheard of. In other words, mental and physical inertia is a large factor in incorrect diagnosis. The practical physician should spend much less time in reading about rare cases, which he is more than likely never to meet in his day's work, and far more time in studying the methods of diagnosis of the few simple conditions which will form ninety-nine per cent. of his practice, learning to recognize them in the various clinical manifestations under which one disease may masquerade as another. In such a profitable study, a short, clear, practical book on the methods of taking histories, of making physical examinations, and of evaluating laboratory reports should be the physician's constant companion.

There is an immense amount of useful information contained in this monograph.

RENAL DISEASE

Modern Methods in the Diagnosis and Treatment of Renal Disease. By Hugh Maclean, M.D., D.Sc. 2d Edition. Philadelphia: Lea & Febiger, 1924.

This small volume has been printed twice since it was first published in 1921. The appearance of a second edition is further evidence that it has accomplished its mission. The book aims to give a short, practical account of the important clinical methods employed in estimating renal function. There have been few changes in the new edition, for there has been little advance in these clinical methods in the last few years. It seems strange that the author, while laying great emphasis on the urea concentration test, makes no mention of the value of the observation of the specific gravity of the urine; and does not recommend the simple dilution and concentration test.

BIOCHEMISTRY

Handbuch der Biochemie des Menschen und der Tiere. Unter Mitwirkung von Geh. Rat E. Abderhalden, et al. Herausgegeben von Prof. Dr. Phil. et Med. Carl Oppenheimer, in Berlin. Zweite Auflage. Lieferung 11: Band I (S. 289-416) Bog. 19-26. Lieferung 12: Band I (S. 417-624), Bog. 27-39. Lieferung 13: Band VI (S. 289-410), Bog. 19-26. Jena: Verlag von Gustav Fischer, 1924.

The second edition of this manual is a monumental work on the biochemistry of man and animals. The long list of prominent collaborators, including the late Jacques Loeb, gives assurance that each topic is treated in a masterly way. Judging by the sample of the three numbers of this series submitted, it is a most comprehensive work. Both the theoretical and practical aspects of biochemical problems are discussed. Greater emphasis is naturally laid upon the application of biochemical study in man than in animals. Other investigators than Germans are also given due notice. The bibliography is very extensive and up to the minute, and each subject is treated exhaustively. Number 11 of the series deals with the pyrimidins and purins, nucleic acids, pigments with pyrrol nuclei and respiratory pigments. Number 12 includes the subjects of carbohydrates and the general chemistry and decomposition products of proteins. Number 13 of the series takes up the general biochemical basic principles of nutrition and the subject of vitamines. To one interested in the problems of physiological chemistry and biochemistry this work is indispensable.

LARYNGOLOGY

Lehmann's medizinische Handatlanten. Band XIV. Lehrbuch der Kehlkopfkrankheiten und Atlas der Laryngoskopie. Von. Dr. L. Grünwald, München. Dritte vermehrte und umgearbeitete Auflage. Mit 112 farbigen Abbildungen auf 47 Tafeln und 35 schwarzen Abbildungen im Text. München: J. F. Lehmann's Verlag, 1925. Pp. viii-312.

The third edition of this textbook on laryngology and laryngoscopic atlas is intended to serve as an aid to the beginner in the study of this subject in the art of observation and interpretation. The colored illustrations leave nothing to be desired as to beauty. Short histories of the cases cited and illustrated are given. The pathology and therapy are not neglected. Both the foreign and native (German) literature are included in the bibliography.

After discussing the anatomy and physiology of the larynx, the various methods of examining the larynx are given, including stroboscopy, stereolaryngoscopy, subglottic laryngoscopy, direct and indirect laryngoscopy, inspection, palpation, auscultation, röntgenography and electrical excitability, with practical suggestions. There is a chapter on the use and treatment of the voice.

The part dealing with pathology and therapy includes that of acute and chronic inflammations, neoplasms, disturbances in motility and sensibility, the affection of the larynx in diseases of the nervous system, combined motor and sensory functional disturbances, circulatory disturbances, hemorrhages, injuries, foreign bodies and malformations. The pathological plates are also beautifully illustrated and extremely instructive.

Too much cannot be said of the great value of this book to everyone interested in laryngology. It is intensely practical.

PERSONAL HYGIENE

The Foundation of Health: A Manual of Personal Hygiene for Students. By William Bernard Sharp, S.M., M.D., Ph.D., Professor of Bacteriology and Preventive Medicine in the Medical Department of the University of Texas. Bibliography, Illustrations, Diagrams. Philadelphia and New York: Lea & Febiger, 1924. Pp. 256.

The preface to this practical little book tells us that it is designed for use in early college years, and is based upon courses prepared for juniors at the University of Chicago and for students entering upon the study of medicine at the University of Texas. The text includes the middle ground between the strictly applied and the physiological methods of teaching hygiene.

POETRY

Flowers From My Garden. By Percy Hill. London: Arthur H. Stockwell, 1925.

This is a small book of verse written by a country dweller which has been inspired by the simple hardy flowers in his garden. The scene is laid in the country district of one of the most rural parts of England, the county of Norfolk, placed among fields with a babbling brook and a setting of trees and woods. The flowers are country flowers, such as flourish in such surroundings, and to each one a short poem is inscribed. The opening lines tell of the author's garden in April.

The idea of a book of poems devoted wholly to flowers is both pretty and novel. It may be said that the poetry, while metrically excellent, expresses in tuneful numbers the sentiments of the garden lover. Flowers lend themselves readily to poetical similes and Mr. Hill has successfully caught and held the spirit of his garden of flowers. Psychologically, in this ultrasophisticated and somewhat distraught age, placidly flowing verses may aid in soothing overstrung nerves and may act as an antidote to the sensational, erotic, and sometimes salacious writings which appear to find favor with a considerable proportion of the reading public.

Medicoliterary Notes.

The Nation's Health for January is a number of unusual interest. Among other articles it contains the following: Study of Drug Addicts in New York State Prisons, by Dr. Abraham Kossef, chief physician of the Clinton Prison, New York; What Is First Aid to the Injured? by Capt. G. R. G. Fisher, director of safety, accident prevention and first aid of the Illinois Manufacturing Association; A program of Education for Parenthood, by Thomas W. Galloway; The Leper Settlement at Palo Seco, by Frederick L. Hoffman; A Program in Sex Education for Boys, by Abraham W. Rosenthal, B.S., M.A., of New York City; and Mental Hygiene in Industry, by Thomas T. Read, safety service director of the U. S. Bureau of Mines.

* * *

Among late publications of Macmillan of interest are: *A Year of Prophesying,* by H. G. Wells, a criticism of the manners and customs of America as he saw them during his recent visit to this country; two plays: *Juno and the Paycock,* and *The Shadow of a Gunman,* both by the Irish dramatist, Sean O'Casey; and *Blind Man's Buff,* by Louis Hémon, author of Maria Chapdelaine. This is a story of sporting life in London, and so in the most different style possible from Maria Chapdelaine.

* * *

Now that the dome of St. Paul's of London has been declared unsafe, and the leaning towers of Pisa condemned, other public buildings are succumbing to the epidemic. The

last reported to date is the roof of Bath Abbey. A report from the Natural History Department of the British Museum states that specimens taken from the abbey roofs and submitted for examination are undoubtedly death watch beetles. The wood must be badly infested with these, and in many places is in a dangerous condition. Sir Charles Nicholson, the famous architect, has suggested that the ravages of the beetle may be checked and counteracted by turning on the roof timbers above the stone vaulting a powerful vacuum cleaner.

* * *

Announcement has been made of the winners of the hospital essay contest on the subject of The Interrelation of Hospital and Community, conducted jointly by *The Nation's Health* and *The Modern Hospital*. Dr. Edward A. Fitzpatrick, dean of the graduate school and educational director of Hospital College at Marquette University, was awarded the first place. The award carried with it a purse of $300. Lucius R. Wilson, superintendent of Barnes Hospital at St. Louis, was the second prize winner and received $150. Dr. D. R. Richardson, superintendent of the Providence City Hospital, of Providence, received the third prize of $100. Honorable mention was given to John R. Howard, Jr., superintendent of the New York Nursery and Children's Hospital; H. J. Southmayd, assistant superintendent of Mt. Sinai Hospital, Cleveland; and Miss Zella Nicholas, R.N., graduate of Mt. Sinai Hospital, New York. The judges in the contest were Michael M. Davis, Jr., Willard C. Rappelye, and Dr. Haven Emerson.

* * *

In commenting on the attitude of indifference manifested toward the child labor situation in Great Britain, an editorial writer in the *Manchester Guardian Weekly* says: "The true obstacle is that on the matter the national conscience is blunt to brutality. We are a nation of civilized cannibals, who differ from uncivilized cannibals only in that, while they devour their enemies, we devour our children; and incidentally, as the figures of unemployment show, make ourselves very sick in the process. This habit of passing successive generations of children through the fire in honour of whatever divinity takes pleasure in the ruin of boys and girls, has attained the dimensions of a public scandal." These are words that it would be well for some of the rest of us to ponder!

* * *

The American Social Hygiene Association, with Dr. Haven Emerson as consultant, has made a study of the facilities provided for the prevention and treatment of gonorrhea and syphilis as a part of the preliminary inquiry necessary for the health demonstration program in Syracuse, N. Y.

* * *

The calendar of courses for the spring term of the New School for Social Research includes religion and its philosophies, by Horace M. Kallen; racial groups in Greater New York, by A. A. Goldenweiser; problem children, by Bernard Glueck; crime and punishment, by A. A. Goldenweiser; problems in psychopathology, by Frankwood E. Williams; technic of influencing human behavior, by Harry A. Overstreet; dominant ideals of Western civilization, by Horace M. Kallen; psychological problems of social reconstruction, by Everett Dean Martin; formation of racial and national character, by William A. Thomas; primitive life, by A. A. Goldenweiser; and science and contemporary thought, by Morris R. Cohen.

* * *

It is reported by the Metropolitan Life Insurance that there is a well defined pneumonia region in the United States, namely New England and the Middle Atlantic States, together with two other seaboard states, Delaware and Maryland. The combination of humidity and low temperature is probably the cause. Pennsylvania shows the highest mortality rate from pneumonia, however, which is probably due to the occupational hazards of coal mining and the manufacture of iron and steel.

* * *

One of the most recent of the Macmillan publications in London is *Prison Reform at Home and Abroad*, by Sir Evelyn Ruggles-Brise, president of the International Prison Commission. A summary is given of the work accomplished by all the Quinquennial International Prison Congresses held since 1872. The author emphasizes in this book, as in his former writings, the view point that penal reform should be concerned less with prison reform than with keeping offenders out of prison altogether.

* * *

A carefully selected bibliography on pollution of waters has been prepared by the New York Public Library. The material included is divided into general industrial wastes, oil pollution, New York City and New York State's pollution, and the Passaic Valley sewer pollution. Copies of the bibliography may be bought from the Public Affairs Information Service.

Automobiles kill twenty thousand yearly in the United States. Nearly twenty times as many as they killed in the Battle of Culloden, which ended the hopes of the Stuarts to gain the throne of the British Empire.—*N. Y. World.*

* * *

Three million rats were killed in one week in London. The week ended November 15, 1924, and school boys, professional rat catchers and private citizens did the killing. One vermin chasing company is reported to have accounted for eight hundred thousand. The occasion was the inauguration of rat week. On its close London sanitary officials made a plea that the war on rats be continued until the body of London's last rat is given a place in the City Museum.—*Nation's Health.*

* * *

Recent publications of interest to medical science are *Now That I'm Fifty*, by Albert Payson Terhune (Doran); *The Physiology of Exercise*, by Dr. J. H. McCurdy (Lea & Febiger); *The Biological Foundations of Society*, by Arthur Dendy (Appleton); *Lighting in Relation to Public Health*, by Janet Howell Clark (Williams & Wilkins); *Immunity in Natural Infectious Diseases*, by F. d'Herelle (Williams & Wilkins); *The Child Health Library*, edited by John C. Gebhart (Hass); *The Education of Handicapped Children*, by J. E. Wallace Wallin (Houghton); *International Clinics*, v. 4 (Lippincott); *The Internal Secretions*, by Dr. Arthur Weil (Macmillan); *The Fruit of the Family Tree*, by Albert Edward Wiggam (Bobbs-Merrill); *Eyeless Sight*, by Jules Romain (Putnam); *Scientific Research and Human Welfare*, by Franklin Stewart Harris (Macmillan); *The Distribution of Physicians in the United States*, by Lewis Mayers and Leonard V. Harrison (General Education Board).

* * *

A meeting was recently held in London to advocate legislation against the abuse of all kinds of animals used for entertainment in theatres, circuses, rodeos, etc. A resolution was carried urging the government to afford facilities for the immediate passage into law of a bill providing for such legislation.

* * *

The twenty-first annual report of the Bellevue and Allied Hospitals of the City of New York covering the year 1922 has recently been issued.

* * *

A bill is now pending in Denmark known as the Steincke bill, which proposes to allow a physician "to release a hopelessly ill person from severe and inevitable sufferings." Under the old law the taking of a patient's life at his special request came within the designation of manslaughter or murder.

* * *

Child labor seems to be assuming the dimensions of a world problem. In view of the recent activities in this country in regard to this social menace, it is of interest and significance to note that a campaign is under way in Great Britain to rectify the condition of the two and a half million young people between fourteen and eighteen employed full time in industry and save them from the serious physical, intellectual and moral deterioration that usually attends such a condition. In China women and children are being exploited under a horrible state of affairs. The latest report of the Child Labor Commission of the Municipal Council of Shanghai describes how children are "sold" into domestic service, and as "slave children are employed in native brothels and trained to prostitution." In the mills, children of six work twelve hours at a time, on day and night shifts, frequently standing the whole time. Many of them are brought from country districts by contractors and their conditions of life are practically those of slavery.

Abstracts from Current Literature

PEDIATRICS

Dislocation of Hip in Childhood.—C. C. Choyce (*British Journal of Surgery,* July, 1924) analyzes all recorded cases up to January, 1924, a total of fifty-nine, and as a result of his analysis advises guarded prognoses as to ultimate changes. For limping is apt to recur after a period of about a year, and pseudocoxalgia and similar changes may then be found.

Tumors of Mediastinum in Children.—L. W. Smith and J. S. Stone (*Annals of Surgery,* May, 1924) report two cases of mediastinal tumors in children. The difficulty of differential diagnosis is emphasized, requiring the use of modern laboratory methods. The only treatment of these tumors is surgical, if they present symptoms due to pressure. A review of the other mediastinal dermoid cysts and solid teratomata in children is presented and a discussion of their etiology is given.

Factors Concerned in the Etiology of Tetany in Children.—Grace H. Anderson and Stanley Graham (*Quarterly Journal of Medicine,* October, 1924) state that active tetany is always accompanied by a diminished calcium content of the serum, there being no relation, however, between ihe severity of the tetany and the decrease of the calcium. Latent tetany may or may not be accompanied by a low calcium content of the serum. The production of acidosis invariably leads to the disappearance of the signs of tetany, irrespective of a rise in the calcium content of the serum. The carbon dioxide combining power of the venous plasma is within normal limits in infantile tetany.

Effect of Diet on the Development and Extension of Caries in the Teeth of Children.—May Mellanby, C. Lee Pattison and J. W. Proud (*British Medical Journal,* August 30, 1924) demonstrated that when children are fed on a diet which has been shown in the case of puppies to result in the formation of well calcified teeth, then the initiation and spread of caries take place at a slower rate than in the case of similar children fed on diets not having such potent calcifying activity. The diet giving the best results is rich both in calcium and calcifying vitamines, and contains comparatively little cereal, none of which is in the form of oatmeal.

Pyelitis in Infancy and Childhood.—V. B. Dowler (*Canadian Medical Association Journal,* January, 1925) says that pyelitis is often a disease of infancy and childhood, that its presence is frequently overlooked, and urges that a microscopical examination of the urine should be made in every case of illness with fever during the early years of life. He thinks it a good plan to suspect pyelitis in any recurrent fever of obscure origin, for widely fluctuating fever with vomiting and diarrhea and negative physical findings are the commonest symptoms presented. He considers the use of potassium citrate in the treatment of the disease to afford an efficient means of ensuring a speedy and lasting recovery. A fatal termination of the disease is unusual.

Nephritis in Childhood.—Charles E. Sundell (*Clinical Journal,* October 29, 1924) says that the chief change in recent years in our views on the dietary control of nephritis is realizing that proteid is not as dangerous as was supposed, and that restriction of the salt intake is of greater importance in many cases. Especially is this true in the most common form of nephritis in children—the large white kidney. In such cases a diet rich in protein has been given with benefit on the assumption, borne out in practice, that it should help to make good protein wastage, promote diuresis and diminish edema. Diuretics are of little value in most cases, and in acute inflammation are directly harmful to the kidney cells. Some patients remain obstinately edematous for months in spite of the customary packs and purges. In these, small doses of pituitrin are occasionally of great help, but the question of decapsulation of the kidney may be considered; observers of repute have described numerous cases where this operation has had happy results. In any case of chronic nephritis in childhood where in spite of all our efforts kidney function cannot be restored, and the child is slowly but surely losing ground, decapsulation should certainly be advised.

Lymphoid Hyperplasia of Appendix in Children.—T. A. Smith (*Annals of Surgery,* June, 1924) points out the difference in symptomatology of lymphoid hyperplasia from acute inflammation of the appendix. It may be said that subacute or chronic appendicitis, usually of the recurrent type, occurs in approximately ten per cent of children with appendiceal symptoms. In the great majority of these cases the symptoms are due, not to an inflammation of the appendix, but to excessive hyperplasia of the lymphoid tissue in its walls, which symptoms are promptly and permanently relieved by removal of the appendix. Furthermore, as the majority of these cases conform to a recognizable syndrome, lymphoid hyperplasia should be considered as a clinical entity among diseases of the appendix.

Basal Metabolism in Childhood.—In the endocrine disturbances of childhood determination of basal metabolism is said by H. Janet (*Journal de médecine Française,* June, 1924) to furnish valuable indications. While hyperthyroidism is rare in childhood in the form of typical goitre, still, in the course of growth and particularly at the time of puberty, increased metabolism is often witnessed as a manifestation of mild thyroid dysfunction. In typical cases this can be reduced fifty per cent by administration of thyroid preparations. Delayed growth appears least capable of modification from the viewpoint of metabolic exchange. Although basal metabolism is lowered in cases of pituitary insufficiency as well, it is far less so here than in thyroid deficiency.

Treatment of Goitre in Infants.—F. Hamburger (*Münchener medizinische Wochenschrift,* December 26, 1924, reports two cases. The first was in a newborn child with a conspicuous goitre greatly interfering with respiration. For eight days one seventieth of a grain of sodium iodide was given daily. On the fourth day the gland began to diminish and by the eighth became normal in size; but diarrhea set in and the child died on the eleventh day, although the iodine had been stopped from the eighth. The author believes iodine administration to young infants should not be continued after the first sign of improvement is seen. The second case was in a child of eight months, whose breathing was also impeded by a goitre. One seven hundredth only of a grain of sodium iodide was given and repeated on the second and fourth day, each time accompanied by a minute dose of thyroidin. The gland diminished to normal size in a week.

Icterus Gravis of the Newborn.—The observations of Paul Klemperer (*American Journal of Diseases of Children,* August, 1924) lead to the conclusion that, in one group of fatal cases of jaundice in the newborn, the icterus is due to a destructive process of the liver; in another group, however, it has to be considered as a prolonged icterus neonatorum of anhepatocellular origin. These conclusions warrant certain suggestions to the pediatrist. The early differentiation in cases of jaundice between the serious type of hepatic jaundice and the milder form of icterus neonatorum is of importance. It can be accomplished by the examination of the blood serum for bilirubin with the Van der Bergh test. In cases of icterus of hepatic origin, a rational therapy should be tried to protect the liver against further destruction by sustaining its glycogen reserve. The beneficial results of glucose transfusion in mushroom poisoning and in toxemia of pregnancy, which aim toward the same point, suggest the same therapy in cases of severe jaundice in the newborn.

Large Thymus with Cyanosis in the Newborn.—E. T. Evans (*Surgery, Gynecology and Obstetrics,* October, 1924) believes that in newborn infants who exhibit cyanosis, whether constant or intermittent in attacks, in the absence of other definite cause, persistent large thymus should always be suspected. Such infants, even in extremis, should be given the benefit of x ray or radium therapy. Plates should be taken before and after treatment, to follow results. However, negative plates do not mean no thymus pressure, as it is anteroposterior thickness and weight of thymus, not width, which causes pressure unless the symptoms are due to an endocrine substance. Diagnosis of bronchopneumonia, obscure intracranial hemorrhage, and

congenital heart disease should not be made without more seriously considering persistent large thymus as a cause of symptoms. Because of recent work indicating persistence of the thymus gland as a relatively normal condition, cessation of symptoms following x ray treatment must be considered the more reliable criterion of diagnosis rather than the positive x ray picture. Some röntgenologists believe that a large thymus cannot be demonstrated, but autopsy findings have revealed them repeatedly, and certainly the abnormally wide mediastinal shadow diminishes in size under treatment coincident with the improvement in respiratory and circulatory distress. In some instances it is very difficult to demonstrate the enlargement, especially if it is in the anteroposterior direction. At any rate, if radiation produces appreciable benefit we feel that we are justified in treating all such doubtful cases.

The Lange Gold Chloride Reaction on the Cerebrospinal Fluid in Infants and Young Children.—C. G. Grulee (*American Journal of Diseases of Children,* August, 1924) reports that in congenital syphilis, the colloidal gold reaction in the spinal fluid may assume at times the same degree as that shown in cases of paretic dementia. Congenital syphilis varies rather frequently from the usual reaction, that is, a fluid which shows the greatest reaction in dilutions of 1:40 and 1:80. There is no regular agreement between the blood Wassermann and the Wassermann and colloidal gold reactions in the spinal fluid. There may be a strong reaction both to the Wassermann and to the colloidal gold solution in the spinal fluid with a negative blood Wassermann. Tuberculous meningitis more nearly conforms to the reaction with greatest intensity in dilutions of 1:160 and 1:320. It may, however, vary considerably from this in certain cases showing a progressive variation as the meningitis extends. Other conditions which may be easily confused with tuberculous meningitis, may show a colloidal gold reaction not dissimilar from that which is seen in certain cases of tuberculous meningitis. There is no definite reaction in most cases of idiocy and epilepsy.

Relationship of Rickets to Light.—A. B. Marfan (*Presse médicale,* January 24, 1925) does not believe it justifiable as yet to conclude that lack of sunshine, and particularly of the ultraviolet rays, is the principal or sole cause of rickets. If this were the case, it would be difficult to account for the fact that rickets is as common in the country as in the cities and in Italy as in Northern countries, and that it is unknown in Greenland, where night is practically continuous for four months in the year and where syphilis and artificial feeding are not observed. Lack of sunlight may, however, be put down as a predisposing cause of rickets. In France, it is not the main cause of rickets. The favorable effect of the ultraviolet rays in rickets is exerted first of all upon general nutrition. After a few exposures the appetite improves, sleep is more restful, the weight increases, and the red cells and hemoglobin show a notable rise. When rather old rickety children unable to walk are treated, they often begin to walk after about ten exposures. Aside from craniotabes, which shows rapid consolidation under these rays, their action on the bony deformities is not very apparent, though upon xray observation the mottled aspect of the end of the diaphysis is seen to lessen or disappear, and the wavy cuplike outline of the end of the diaphysis, which is characteristic of rickets, often undergoes a rather rapid change, becoming straight.

The Debilitated Child.—C. Wilfred Vining (*Lancet,* August 2, 1924) calls attention to the frequency with which the same type of sign and symptom is found in the histories and physical abnormalities in the debilitated child. These signs and symptoms are believed to be due to two main factors—nutritional and toxic, tonelessness being due to the former and many of the symptoms to the latter. The nutritional factor may be due to a long standing dietetic defect, together with the results of a chronic intestinal dyspepsia, while the toxic factor is believed to be due to absorption of toxins from the throat and bowel, especially the latter. The unhealthy throat may be secondary to the general tissue cell defect brought about by the nutritional factor.

In the relationship of tuberculosis, nerve disorder and rheumatism, the debility is in the large majority of cases not due to tubercle, although the possibility of strictly localized tuberculous infection in some group of glands cannot be altogether denied. It is believed that in these cases the infection is secondary to the preceding lowering of resistance and tone. The nervousness and nervous disorders of these children is secondary to the nutritional defect of the nerve cell and its irritation by toxins. The rheumatic infection of childhood appears in most cases to be ingrafted upon a preceding defect in health, which proves to be similar to the defects in health shown by the debilitated child, and it is suggested that the prophylaxis and control of the rheumatic diseases the child's health in its earliest years is of the first importance, and emphasis is laid upon the great importance of a well balanced diet and the avoidance of chronic intestinal dyspepsia.

Some Diseases of the Blood in Children.—J. P. Crozer Griffith (*Archives of Pediatrics,* August, 1924), as a result of some clinical studies, draws the following conclusions:

1. The blood picture of chlorosis is of frequent occurrence in infancy and childhood, and such cases should properly be designated chlorosis.
2. The administration of iron, without other treatment, is often of striking benefit in these cases and in simple anemia.
3. In disease of the blood in general, certainly in childhood, the symptoms appear to be almost, to a certain extent, interchangeable, or at least kaleidoscopic.
4. Without an examination of the blood a diagnosis is more likely to be mistaken than correct, and that even with it a diagnosis cannot be based upon any one hematological feature; certainly not on alteration in the character of the red cells; any excess either of lymphocytes or myelocytes, a high color index or a low color index.
5. There appears to exist no definite relationship between the degree of alteration of the blood and that of the size of the lymphatic glands and spleen.
6. Variations in the blood picture occur not only between different cases, making the differentiation of the disease present difficult, but from time to time in the same case.
7. In fact, only careful and often repeated examinations of the blood and of the symptoms in general insure our reaching a correct diagnosis.

Prognosis of Sequelæ of Epidemic Encephalitis in Children.—Roger L. J. Kennedy (*American Journal of Diseases of Children,* August, 1924) gives the following summary of a study of sixty-one cases of residual epidemic encephalitis in children under fourteen years of age, fifty-two of which were traced from the time of their first visit until the present:

Twenty-one patients, sixteen of whom were traced, presented the parkinsonian syndrome. None was improved; the condition of two was stationary, and of fourteen worse. One died from an intercurrent infection. The prognosis in this condition is not bad as regards life, but poor as regards improvement or recovery.

Twenty-three had changes in behavior and personality. Six were improved, and seventeen showed no improvement, or had become worse. The lack of restraint exhibited by these children does not necessarily imply any great degree of mental impairment.

Nineteen presented disturbances of sleep. Nine of these are now sleeping practically normally, three still show more or less disturbance, and seven are the same or worse.

The respiratory syndrome occurred in this series much more commonly than is indicated by the literature. Two of seventeen children who had this sequela are well; three are apparently improving, and the condition of twelve is unchanged. In none has the condition become worse.

Foreign Bodies in the Air and Food Passages of Infants and Children.—Russell S. Rowland (*American Journal of Diseases of Children,* August, 1924) states that the initial symptoms of foreign bodies in the air and food passages of infants and children are often not observed, and therefore no history is obtained, or the history may be obtained and not given sufficient consideration. Usually the higher the foreign body is lodged in the respiratory tract, the more pronounced the symptoms; while the lower down it is, the more marked the physical signs. Frequently in tracheal cases after the initial choking and strangling there is a symptomless period and then the tracheal symptoms develop. Esophageal foreign bodies of considerable size may produce no symptoms at first, but if allowed to remain in the esophagus for any length of time they may cause dangerous ulceration. The position of foreign bodies in the esophagus, as shown in the x ray plate, in relation to those in the trachea should be remembered.

Foreign bodies in the stomach rarely produce symptoms and no signs. With bronchial foreign bodies signs of a partial or complete obstruction of a bronchus are diagnostically of the most importance. It is a characteristic sign to have a multiplicity and changeability of symptoms. Sometimes organic bodies may produce sudden violent attacks, at other times the physical signs and x ray findings may not develop until several weeks after the accident. Small metallic bodies frequently cause no reaction at all, while large metallic objects may produce symptoms simulating tuberculosis, or some other chronic lung infection. Aspiration of nursery powders may be extremely dangerous. Certain objects cannot be demonstrated by the x ray, while others make no shadow on the plate, and still may give a diagnostic picture and definite signs and symptoms. Endoscopy should be resorted to in suspicious cases not demonstrable by x ray. An early diagnosis may be of vital importance.

A fuller appreciation of these facts and of the importance of the history, signs and symptoms will help us to recognize more promptly some of the unusual foreign body cases; it will assist us to differentiate the acute conditions from pneumonia and the chronic cases from tuberculosis and empyema. It will remind us that the etiological factor in bronchiectasis and gangrene of the lung may be a foreign body, and that a persistent wheeze is not always the result of anaphylactic or thymic asthma, but may sometimes be due to a foreign body.

GASTROENTEROLOGY

Invagination of the Jejunum in Gastroenterostomy.—H. Vulliet (*Schweizerische medizinische Wochenschrift,* July 24, 1924) reports that the invagination of the jejunum in gastroenterostomy may occur after the classical operation, that a fresh gastric ulcer need not be present, and also that the vomiting following the operation plays no important part in the occurrence of this complication.

Biliary Infections.—D. P. D. Wilkie (*British Medical Journal,* August 2, 1924) finds that failure to detect and remove a stone from the common duct is the usual cause of recurrent symptoms after operation, and, where doubt exists, incision and exploration of the duct should invariably be practised. The condition of the pancreas, appendix, the stomach, and duodenum must be investigated, as coincident lesions in these organs are by no means rare and may require to be dealt with, in order that complete recovery may follow. Only with good anesthesia and a free incision can the complete pathological picture be displayed and adequate treatment be safely employed. Inadequate operation can only bring disappointment to the patient and discredit to surgery. The removal of several hundred gallstones will avail nothing if the stone which was the real cause of the trouble be left behind. To remove one or more calculi and leave an infected, thickened, and functionless gallbladder may give the patient some relief but will not result in a cure, and is evidence of a failure on the part of the surgeon to appreciate the intrinsic mural character of the gallbladder infection. Timely preoperative diagnosis and complete assessment of pathological change at operation are the two essentials for the successful treatment of biliary infections.

Relationships of Diseases of the Gallbladder to the Secretory Functions of the Stomach and Pancreas.—H. Ernest Griffiths (*Lancet,* August 2, 1924) calls attention to the close developmental origin and nervous association of the gallbladder, pancreas, pylorus and first and second portions of the duodenum, resulting in closely allied physiological actions and pathological reactions. The best clinical example of this relationship is pylorospasm. Irritation of the mucosa of the gallbladder results in a reflex irritability of the vagus, shown especially by an increase in the amount and acidity of the gastric juice in the stomach, associated with relaxation of the pylorus and regurgitation from the duodenum. Hyperchlorhydria was found associated with regurgitation in ninety per cent. of the cases of cholecystitis with or without gallstones. The duration of the inflammation and its degree are commensurate with the intensity of the secretory deficit in the stomach. True hyperchlorhydria occurring in inflammatory lesions of the gallbladder appears to be due to intercurrent disease, although it occurs regularly in advanced cases of carcinoma of the gallbladder.

Acute pancreatitis is generally a sequel of pancreatic lymphangitis. Here there is already congestion of the pancreas, and a tendency to vomit. Spasm of Oddi's sphincter is accompanied by regurgitation of bile into the pancreatic duct. Vomiting or straining increases the pressure of the bile, resulting in hemorrhage from the congested bile capillaries and liberation of the ferment trypsin, the activity of which is increased by the presence of bile. The regurgitation of bile is not a prerequisite of hemorrhage, as it may be due to congestion alone. Infection in the gallbladder is always associated with gastric disorders and subsequent pancreatic disturbances.

Relation of Medical to Surgical Treatment of Gastric and Duodenal Ulcers.—Frank H. Lahey and Sara M. Jordan (*Boston Medical and Surgical Journal,* September 25, 1924) present as their conclusions:

1. It is desirable to exhaust the possibilities of adequate medical measures for gastric and duodenal ulcers before submitting them to surgery.
2. Medical measures in gastric and duodenal ulcers, in addition to their ability to relieve, aid in confirming or disproving the diagnosis and, furthermore, are of real value in certain cases in demonstrating the need for surgery.
3. Preliminary medical management with rest in bed makes operation safer and easier in many cases later to be submitted to surgery.
4. Gastroenterostomy even with its possibility of failure to cure and of subsequent gastrojejunal or jejunal ulcer is still the most useful of all the gastric operations. The fact that when its employment as a curative measure in gastric or duodenal ulcer fails, it still represents an already accomplished part of the radical operation makes it then only a complete failure when gastrojejunal or jejunal ulcer follows its employment.
5. Radical resections should be reserved for those cases where the indications justify the risk of its employment as a primary measure.

Surgical Treatment of Gallbladder Disease in Diabetics.—Daniel Fiske Jones, Leland S. McKittrick, and Dwight L. Sisco (*Boston Medical and Surgical Journal,* October 16, 1924) say that operation for gallstones is especially indicated in the diabetic, but many patients are not operated on owing to the teaching that the dangers of operation are too great. They believe that the diabetic patient can be operated upon for gallstones with practically no more danger than the nondiabetic patient, provided all conditions are propitious. The evidence supports the statement that preventive surgery in diabetics is not only justifiable but rational. Gallstones should be removed as soon as a positive diagnosis can be made, and acute cholecystitis should be treated the same as infections of any kind in diabetics, that is, as an emergency.

Chronic Appendicitis.—F. N. G. Starr (*Northwest Medicine,* September, 1924) classes these cases for purposes of treatment into four groups.

1. The cecum may be mobile without much atony but it produces a drag on the superior mesenteric vessels and thus crowds the duodenojejunal junction. One must bear in mind that, when the cecum is mobile and becomes atonic, it reverts to that of prehistoric man or to the type of the herbivorous animal. Therefore, meat must be eliminated from the diet. In order to change the bowel flora as quickly as possible from the flora of the carnivorous to that of the herbivorous animal, a yeast cake may be eaten night and morning. Flaxseed added to the diet ensures a daily bowel evacuation. Abdominal massage and physical drill helps, and when in the upright position these patients should wear a corset with an abdominal "lift." When one has not easy access to a good corsetmaker, an ordinary abdominal belt with an oblong rubber bath sponge under it serves the purpose admirably. Under such circumstances the alteration from semiinvalidism to rude health is sometimes very striking. This method of treatment, I should say, is applicable to well over four fifths of the patients seen.
2. Failing to get physical efficiency in this way, in the early mild cases where the cecum is still an abdominal organ, probably all that is required to bring about a cure is the removal of the appendix, the sharp division of the ileal link, combined with plication of the cecum, after dividing by sharp dissection a constricting fibrous band at the junction of the cecum and ascending colon over the outer leaf of the mesentery, as well as a sigmoid band fixing the sigmoid to the left broad ligament in the female, or the pelvic wall in the male.
3. When the cecum is a pelvic organ, resembling the herbivorous type, and is in a similar stage of atony with

marked ileocecal regurgitation, the removal of the appendix with plication of the cecum and then a burying of the plicated margin into a slit three or four inches long in the posterior parietal peritoneum, leads to a cure. There was no mortality in the first hundred cases. There have been two deaths apparently from pulmonary embolus in the second hundred. Afterward the patients gained in weight from ten to thirty pounds, with increased efficiency and a loss of much of the neurasthenia. In fact, some practitioners have complained that such treatment of their patients has destroyed a weekly source of revenue.

4. In the advanced cases, where there is marked atony with third degree incompetency of the valve, and long continued ill health, where the appendix has been removed and a subsequent series of adhesion breaking, health breaking, and heart breaking operations have already been done, nothing short of a radical resection of the terminal ileum, cecum, and ascending colon, with an end to end anastomosis.

Clinical Aspects of Unsuspected Hypertoxic Appendicitis.—E. St. Jacques (*Canadian Medical Association Journal,* September, 1924) in summing up his remarks, says that acute appendicitis is sometimes hypertoxic and is then rapidly gangrenous. The toxicity induces acute infectious enteritis almost immediately from the onset. The diarrhea appears as the dominant characteristic of these cases. Pain is present, at the onset localized at McBurney's region, but is rapidly generalized throughout the whole of the abdomen on account of the acute enteritis. The degree of pain is moderate at McBurney's point at the onset, usually escaping the attention of the patient on account of its spreading rapidly to the whole abdomen, by reason of the enteritis. Muscular defense or rigidity is scarcely present at the onset, but becomes well marked when diffuse peritonitis sets in. The pulse is usually rapid from the start, a condition due to the infectious character of the disease. The temperature may be only moderate, sometimes subnormal. The general condition of the patient is decidedly bad from the onset. As Comby and Dieulafoy have well pointed out in their clinical lectures, this particular variety of acute hypertoxic appendicitis is not infrequently met with in children, but may also be seen in adults; its course is rapidly fatal if operation is not performed early. The etiological factors are the presence and abnormal activity of bacteria, the coli bacilli not infrequently, a variety of streptococcus frequently, and in the rapidly hypertoxic variety, anaerobic bacilli, Welch's or some other. Lastly, the clinical fact must ever be borne in mind that in children, so prone to pneumococcus peritonitis, which is usually primary without a former acute pneumococcus infection, this type of appendicular peritonitis is in the vast majority of cases accompanied at the very onset by diarrhea with persistent offensive stools. Acute appendicitis imposes surgical intervention and the quicker the better.

Traumatized Bile Ducts.—J. F. Erdmann (*American Journal of Surgery,* May, 1924) discusses the anatomy of the cystic duct, and the effects of trauma upon it. He gives an illustrated series of cases with the following operative technic which he used and recommends for all complicated or long standing traumas. The proximal end being found, the tube or catheter is introduced one to two inches into the liver and sewed in with one or two chromicized catgut sutures, grasping the tissues of the duct and the capsule of Glisson in the needle bite. The protruding catheter or tube is cut off so that six to eight inches remain exposed. The duodenum, in the instances when the distal duct is not found, is then attached below the hepatic duct fully one quarter of an inch to the peritoneum covering the liver (capsule of Glisson) with two to four sutures closely placed. A flap is cut, in character like that in a gastroenterostomy. An opening is made through the muscular and mucous coats large enough to admit the tube which, by means of its six to eight inches of length, is passed around into the transverse portion of the duodenum, so that the tube has no kink at its entrance into the liver and gut. The musculomucous posterior area is sewed to the edge of the hepatic opening, and the anterior to the upper edge of the hepatic opening. Finally the peritoneum of the duodenum is sewed to the liver above the tube. The well is wiped dry, a rubber tissue drain is placed in, and the abdominal wall is sutured. The subsequent care includes early removal of the drain.

Following the operation there is a rapid loss of jaundice, a marked rapid mental change and a pronounced gain in weight. The recurrences must be ascribed to contracture of the newly formed canal following the passing of the tube before proper epithelization takes place. Therefore all attempts at fixation of the tube should be made, contrary to the early feeling that some material should be attached to the distal end of the tube to promote its removal by peristalsis. The great difficulty is that peristalsis will pull and push the tube without any accessory. That the tube may become plugged and obstruct the flow of bile must be considered and this requires removal with or without reintroduction of another.

Relationship Between the Islets of Langerhans and the Zymogenous Tissue of the Pancreas.—Swale Vincent (*Lancet,* May 10, 1924) finds that the islets of Langerhans are not separate and distinct organs. They represent temporarily modified portions of the secretory tubules of the pancreas. The differentiation observed in the cells as a result of some forms of staining may point to different stages of activity and not indicate two distinct types of cell. Moreover, these are signs of a similar differentiation among the cells of the zymogenous tissue. The islets are anatomically continuous with the zymogenous tubes, and the two kinds of tissue may be seen to merge one into the other. During inanition and under other circumstances the amount of islet tissue is regularly and markedly increased.

Spirochetosis Icterohemorrhagica.—G. Lovell Gulland and George Buchanan (*British Medical Journal,* February 23, 1924) conclude from their clinical observations that the leptospiral organisms found in man and rats produce lesions typical of infectious jaundice when inoculated into guineapigs. The result of the inoculations is fatal in seven to fourteen days. Subinoculation into the same species, with either human or rat strains from dead infected guineapigs, is more rapidly fatal in both cases, the period being five to six days. The two organisms isolated from one case (man and wild rats) were morphologically identical. The organism has been cultivated. Its characteristics in dark ground illumination consist of very minute regular spirals throughout its entire length, and a hook at one or both ends. The hooked end rotates in the manner of a propeller, and progress occurs in the direction of the unhooked end. If both ends rotate it remains practically in the one place. The pathogenic action, morphology, and behavior in culture of the leptospira up to the present time show it to be identical with the Japanese, European and American strain described and compared by Noguchi.

Gallstone Treated by Cholecystostomy.—E. MacD. Stanton (*International Journal of Medicine and Surgery,* September, 1924) presents a study of the end results of a hundred gallstone cases, which are in brief as follows:

1. The first requisite of successful gallbladder surgery is a correct diagnosis. The end results following operations for true gallstones are highly satisfactory. In the absence of gallstones the end results are certainly no better and possibly no worse than diagnoses on which they are based.

2. In gallstone cases cholecystostomy can be depended upon to give excellent results provided that all of the stones are removed from the gallbladder and ducts and that the cystic duct is left in a condition to remain patent.

3. All of the evidence presented by this group of cases indicates that the tendency of the gallbladder to overcome infection and to repair the damages produced thereby is similar to that of all other hollow viscera, and that in the absence of persisting obstruction the subsidence of the infection and a return to a condition of satisfactory functional repair can be confidently expected.

4. The twenty-six cases of acute empyema of the gallbladder studied by the writer, in which all of the stones were removed at the primary operation and which were treated by cholecystostomy, yielded end results fully up to the standard of other groups. This would indicate that the surgeon confronted with an acute inflammatory condition of the gallbladder need have little hesitancy in leaving it if he fears that its removal would necessitate a more dangerous operation than a simple cholecystostomy.

5. In the presence of choledochotomy for common duct stones cholecystostomy has, in the writer's experience, given highly satisfactory end results. In cases in which common duct obstructions have recurred or subsequently developed, the presence of the gallbladder made secondary cholecystenterostomy a safe and satisfactory operation.

6. The available data would tend to indicate that following cholecystostomy for gallstones, recurrence of stones in the gallbladder or ducts can be expected to occur at a rate of something less than one per cent. a year.

Use of Eserine and Strychnine in Postoperative Abdominal Distention.—Karl H. Martzloff (*Bulletin of the Johns Hopkins Hospital,* November, 1924) presents the results of a study of 162 cases subjected to major abdominal operation under ether anesthesia, in which eserine salicylate, grain 1/1000, and strychnine sulphate, grains 1/40, were given hypodermically to each alternate patient immediately on her return to the ward after operation, and every four hours thereafter for eight doses. Of the 162 patients, seventy-four received the drugs, and eighty-eight did not. The following facts appear from an analysis of these cases: Of the patients receiving the drugs, thirty-four developed distention totalling 776 hours, and eleven of the untreated patients developed distention totalling 147 hours. Emesis occurred as a complication in the treated cases in twenty-seven patients, and in the untreated group in twenty-six patients. Voluntary micturition was reestablished in twenty-four hours after operation in forty-four of the treated patients, and in sixty-one of the untreated patients. In studying the relation between postoperative distention, emesis and delayed voluntary micturition, no definite difference was found between the treated and untreated groups. The conclusion is reached that no benefits have been demonstrated from the postoperative use of eserine and strychnine as described, in abdominal operations on the pelvic viscera.

Surgical Treatment of Hepatic Cirrhoses.—W. J. Mayo (*Annals of Surgery,* September, 1924) discusses the various types of cirrhosis and methods of treatment. He believes that in the present incomplete state of our knowledge, cirrhoses of the liver may be divided into two fairly definite groups: 1, portal cirrhosis, the result of deposits of connective tissue around the radicles of the portal vein, causing ascites and hemorrhages from the stomach, and 2, biliary cirrhosis, the result of deposits of connective tissue around the biliary duct system, causing chronic jaundice.

The portal cirrhoses may be of two distinct types clinically; a primary gastrointestinal type, sometimes definitely the result of alcohol, pepper, or other irritating substances taken with food, in which the spleen is not greatly enlarged. In suitable cases, splenectomy and the Talma-Morison operation combined may have value. Splenectomy in addition to the Talma-Morison operation carries an increased risk, however, and before splenectomy is performed, the functional capacity of the liver should be tested. In the secondary splenic type of portal cirrhosis, occurring in the last stages of splenic anemia, splenectomy gives splendid results.

The common forms of biliary cirrhosis are the results of obstructions and infections of the biliary ducts, usually associated with gallstone disease, and removal of these infections and obstructions, in cases not too far advanced, can be expected to result in cure. The spleen is not greatly enlarged in such cases, and splenectomy appears unnecessary. There is a splenic type of biliary cirrhosis, however, chronic in character, in which the splenomegalia is a prominent symptom and splenectomy may be indicated.

Diverticulitis of the Colon.—E. S. Judd and L. W. Pollock (*Annals of Surgery,* September, 1924) present the following conclusions to their study of a number of cases. Diverticulitis of the colon is more common than was formerly believed. There may be a solitary diverticulum in any portion of the colon, or a great many diverticula distributed from the ileocecal valve to the rectum. It is apparently not progressive, and may remain unchanged for years. In many instances it apparently does not cause symptoms. Diverticulitis is a disease of middle life. The condition we speak of as diverticulitis is peculiar to the sigmoid. We have not observed the condition, which is a diffuse edema, inflammation, and swelling throughout all of the tissues of the colon and mesentery, in any other quadrant of the colon. As the inflammation in the diverticula and wall of the colon progresses, an abscess may form and later perforate into the abdominal wall, bladder, or intestine. If the inflammation remains chronic, a tumor composed of fibrous tissue and the products of inflammation develops. It is often difficult to distinguish between diverticulitis of the sigmoid and carcinoma; in a number of the cases the conditions are associated. Just what influence diverticulitis has on the development of carcinoma, we are unable to determine. If the history reveals that the patient has had repeated similar attacks, and has noticed a tumor for a long time, increasing and receding from time to time, the probability is that it is due to a diverticulitis. In some instances, a definite diagnosis cannot be made until the tissues have been examined histologically. Many patients with diverticulitis can be relieved by dietary and medical management. If an abscess forms from the perforation of a diverticulum, or extension of the infection through the wall of the colon, drainage is indicated. If perforation occurs into other regions, an operation is the only procedure that offers relief. If there is any question as to the nature of the tumor, operation is indicated. The mortality from radical operations for diverticulitis has been very high. The difficulty in these cases has arisen from stirring up the infection that existed in the tissues around the colon before the operation. It seems to us from a review of the results in these cases, that the plan of procedure should be a preliminary colostomy for the purpose of caring for any obstruction in the colon, and particularly the reduction of the inflammation in the diverticula by frequent irrigations of the lower colon. Resection of the infected portion can then be made with less risk.

BLOOD AND LYMPH GLANDS

Value of Blood Transfusion in Acute and Chronic Anemias.—Odön Khoór (*Zentralblatt für Gynäkologie* August 2, 1924) summarizes his experiences with blood transfusion after acute and chronic hemorrhages as follows: The functional capacity of the transfused blood was not demonstrated; at any rate, the blood elements disappear, especially the erythrocytes, within twenty-four to forty-eight hours. The transfused blood produces unpleasant, sometimes very severe chills and high fever lasting for days; the transfusion has an inherent danger of hemoglobinuria, aside from that due to thrombosis and air embolism. In addition, the author found neither a mentionable nor a lasting improvement in the blood picture in his comparative studies either after acute or chronic hemorrhages. The transfusion cannot take the place of the lost blood. Its only effect is a stimulation of the erythropoietic system and it simply acts as an homologous serum for the body in place of the physiological sodium chlorid solution used heretofore. Consequently, the author believes that the use of blood transfusion is indicated only in the most selected cases and after careful study. An absolute necessity for it was never encountered.

Chlorides of Serum, Blood, and Corpuscles in Various Pathological Conditions.—H. C. Gram (*Journal of Biological Chemistry,* September, 1924) presents a study of the chloride concentration in serum, cells, and whole blood in cases with low serum chloride and anemias and polycythemias. In the cases with serum chloride higher than normal, the relative corpuscle NaCl in several cases varied markedly in both directions from the relative serum chloride, while the relative blood chloride agrees with the latter to within three per cent. Whether or not the variation in chloride concentration of the serum—which is independent of cell volume—is taken into account, there is no evidence that the chloride concentration in the corpuscles rises and falls with the cell volume percentage.

A Case of Polycythemia Vera with Special Reference to the Familial Features and Treatment with Phenylhydrazine.—Trevor Owen (*Bulletin of the Johns Hopkins Hospital,* August(1924) reports in detail a case of polycythemia vera in which the symptoms were neurological, and the disease was discovered in another member of the patient's family. The patient received phenylhydrazine hydrochloride, 0.1 gm., in a capsule by mouth every day from January 7th to March 1st. There was no gastric disturbance, and since the blood count did not diminish rapidly, and there were no unpleasant symptoms after six days, he was given an extra 0.1 gm. every other day. He received a second course from April 9th to June 17th. The plan for further treatment is to have the blood counted regularly every two weeks for some time, and to give 0.1 gm. doses frequently enough to maintain the blood at a constant level.

Retinal Hemorrhages in Bothriocephalus Anemia.—Martin Cohen (*Archives of Ophthalmology,* July, 1924) calls attention to the fact that in severe anemias which simulate pernicious anemia the bothriocephalus latus may be the causative agent. According to accounts in the literature more than half of these cases show significant retinal hemorrhages, which are numerous, located mainly around the papilla and may be preretinal, circular, and striated. Such hemorrhages are not pathognomonic of bothriocephalus anemia, but are suggestive when associated with secondary anemia of unknown origin.

Transfusion in Osteomyelitis.—M. L. Janes (*American Journal of Surgery,* May, 1924) offers the following conclusions to his study of three cases. Blood transfusion is an essential measure in combating infection, overcoming anemia and emaciation and stimulating the recuperative powers of a patient. The procedure is indispensable in all cases of protracted suppuration involving bone. It should be performed as promptly as possible to ward off degenerative changes in the vital organs of the body resulting from prolonged suppuration.

Blood Coagulation.—E. C. Mason (*Surgery, Gynecology and Obstetrics,* October, 1924) studies the production and prevention of experimental thrombosis and pulmonary embolism, with the following results. Three components, fibrinogen, calcium and tissue extract, enter into the formation of the intravascular, as well as the extravascular clot. Of all agents promoting intravascular coagulation, none is so potent as tissue extract. Purified heparphosphatid has been titrated against the most active tissue extract and found to neutralize the coagulant action of such extract. If clinical thrombosis and embolism are comparable with experimental thrombosis and embolism, the anticoagulant offering so effective protection in one should be of use in the other. The anticoagulant should find a clinical use as an anticoagulant in blood transfusions and also as an anticoagulant in the determination of the blood hematocrit, or wherever the hypertonic action of excess salt is contraindicated.

Lymphatic Leucemia: Age, Incidence, Duration, and Benefit Derived from Irradiation.—George R. Minot and Raphael Isaacs (*Boston Medical and Surgical Journal, July* 3, 1924) present data concerning ninety-eight cases of chronic lymphatic leucemia and fifty-seven of the acute form. End results were studied in eighty cases of the chronic form in patients over thirty years of age, fifty of whom treated by intensive irradiation by radium or x rays, and thirty not so treated. Most cases of the chronic form occur in persons from forty-five to fifty-five years of age. Acute lymphatic leucemia seldom occurs after twenty-five. Both forms affect males about three times as often as females. Both are relatively more frequent in females in the earlier than in the subsequent years of life. The correct diagnosis in the chronic cases was not established on the average until one and four tenths years after the first symptoms.

Irradiation had no detectable effect on prolonging the duration of either form of the disease. The average duration of life, after the first symptom, in eighty chronic cases in which the patients were over thirty years of age, was three and forty-five hundredths years, being essentially the same for the fifty irradiated cases and the thirty that were not.

The chronic disease lasts a shorter time in younger than older persons. About sixty per cent. of the patients in chronic cases live one to four years, and fourteen per cent. six to eight years. In about fifty per cent. of the acute cases the patients died in less than two months after the initial symptoms appeared.

There was a great similarity in the time the different patients first received irradiation as related to the total duration of their disease, indicating that if the disease was destined to be of long duration the patients had insidious symptoms for a longer time than those fated to a short course. The early institution of irradiation as yet does not promise a more favorable prognosis with respect to life extension. Irradiation, properly administered, undoubtedly benefits symptomatically cases of the chronic form though not as much as in chronic myelogenous leucemia.

Moderate or greater general improvement after the first course of irradiation, occurred in forty-seven per cent. of sixty-one cases; rather slight improvement in thirty per cent., and no improvement in twenty-three per cent. The efficiency of ten per cent. was increased strikingly. The chances of improvement are in fairly direct relationship with the time before death that treatment is given.

The beneficial effects of irradiation in acute lymphatic leucemia are but evanescent and slight. Irradiation may induce a better production of the three formed elements of the marrow and lessen the activity of the formation of lymphocytic cells. The hemoglobin level, numbers of blood platelets, and character of the lymphocytes serve more importantly to adjudge the patient's condition than the number of white cells. An aleucemic blood picture may occur when patients are seriously ill.

Irradiation usually causes little or no improvement in the patient when the hemoglobin is fifty per cent. or less, or when outstanding purpura with thrombopenia is present, or when there are many immature and atypical lymphocytes in the peripheral blood.

The effect of irradiation on decreasing the size of lymph nodes or spleen in chronic lymphatic leucemia is apt to be proportional to the amount of improvement in the patient's general sense of well being. Definite exceptions occur but distinct pressure symptoms due to enlarged external or internal lymph nodes were rarely not alleviated.

Treatment should be guided and prognosis formulated from correlated information obtained from the patient's history and physical signs, together with complete blood examinations and basal metabolic rate determinations. By so doing, in spite of irradiation becoming less and less effective and the patient's comfort decreasing as the disease progresses, this therapy is of distinct value and maintains the patient's efficiency usually much better than if no irradiation is given.

Blood Transfusion.—L. B. West (*American Journal of Surgery,* September, 1924) cites the Mount Sinai Hospital records for transfusion of blood during the year 1922. There both the citrate and the stopcock method were used. Chills followed transfusion by the whole blood, or stopcock, method, in thirty-four per cent. of the cases, while in twenty-three per cent. chills followed citrate transfusions. From a review of the literature and from personal experience with various methods the author finds that the citrate method of blood transfusion is the method of choice, especially in surgical conditions requiring transfusion.

Experimental High Intestinal Obstruction in the Monkey.—Russell L. Haden and Thomas G. Orr (*Journal of Expermental Medicine,* January, 1925) present a chemical study of the blood of the Macacus syrichtus species of monkey after the intestine has been experimentally obstructed. The changes observed are variable, but quite similar to those previously reported in man and the dog. All animals showed a marked rise in nonprotein nitrogen and two showed a marked drop in the chlorides, with a less marked fall in the others. There was a rise in the carbon dioxide combining power. No changes were recorded in the uric acid and creatinine. There was no vomiting which affords additional evidence in favor of the authors' theory that the fall in the blood chlorides is concerned in some way with the toxemia.

Cholesterol in the Blood in Cases of Gallstones.—J. M. H. Campbell (*Quarterly Journal of Medicine,* October, 1924) examined the blood of fifty-two persons, in twenty-two of whom disease of the gallbladder was diagnosed. The conclusion is reached that the amount of cholesterol in the blood in cases of gallstones and cholecystitis is within normal limits, provided the subject is not jaundiced. The determination is therefore of no help in the diagnosis of gallstones. This investigation lends no support to the theory that the formation of gallstones is caused by a raised cholesterol content of the blood and bile. It does not exclude the possibility, for it may be that in all the cases examined the active pathological change was over and the gallstone was left as a legacy. The normal findings in some cases of cholecystitis make this unlikely.

Sodium Content of the Blood of the Dog After Experimental Intestinal Obstruction.—Russell L. Haden and Thomas G. Orr (*Journal of Experimental Medicine,* January, 1925) report sodium determinations on the blood of ten dogs after experimental obstruction of the jejunum. Very little change in the sodium content was noted, the total sodium tending to rise rather than fall.

Distribution of Chlorides in the Blood of the Dog After Experimental Intestinal Obstruction.—Russell L. Haden and Thomas G. Orr (*Journal of Experimental Medicine,* January, 1925) undertook this investigation to determine the distribution of chloride in the blood of the dog after experimental obstruction of the jejunum. The chlorides were estimated simultaneously in whole blood, in plasma, and in the cells. The fall in blood chlorides in intestinal obstruction was found to involve both the cells and plasma, and almost equally so. Determinations on whole blood are more desirable than on the plasma. The close agreement in chloride by the iodimetric titration and the Van Slyke digestion method shows definitely that the chloride does not exist in the blood in some undetermined form.

Medicolegal Notes.

ADMISSION OF "WRONG OPERATION" HELD NOT SUFFICIENT TO MAKE SURGEON LIABLE

In an action for malpractice growing out of the employment of defendants by plaintiff to perform a surgical operation on him for the cure or removal of a hernia in the region of the right groin, it was held, Markart v. Zeimer, (Cal. App.) 227 Pac. 683, that where no evidence was offered tending in any substantial way to show that defendants in performing their surgical operation closed the inguinal canal so tightly that it interfered with the action of nerves or stopped the flow of blood to plaintiff's right testicle, or that when the wound commenced healing "the inner walls adhered and grew fast to the bowels of" the plaintiff, it was error, in instructing the jury, to submit these issues to the jury. And where the complaint charged the defendants with a trespass in removing the testicle without plaintiff's consent and against his expressed direction, but no charge was made that the work of removing it was carelessly or unskillfully done, it was held error to submit the question of the degree of skill and care exercised by defendants in the operation.

It was also held error to charge that a physician is liable for the want of "proper" skill and care of his assistant, if any. All that is required of him is that he have the degree of skill ordinarily possessed by reputable physicians practising in his locality.

It was held that an admission by one of the defendants that the operation was a "wrong operation" and a "misoperation" amounted to more than an admission that the operation was not properly done, and that was not sufficient to render him liable. "An admission," the court said: "to be sufficient must be an admission of negligence or lack of the skill ordinarily required for the performance of the work undertaken. This 'wrong operation' may have been deemed right at the time it was performed. If it was so mistakenly performed as the result of a bona fide judgment by a qualified surgeon, he will not be held liable for the unfortunate results of his mistake."

BRIGHT'S DISEASE AS AN EFFECT OF AN ACCIDENT

In a workmen's compensation proceeding the physician who attended the applicant immediately after his injury testified to an injury to the applicant's kidneys which he attributed to the effects of the accident; and the Industrial Accident Commission's medical director, in his report upon the case, and referring to the fact that three hours after the accident the symptom of hematuria was observed in the patient, declared that that circumstance was good presumptive evidence that damage to the kidney occurred. The evidence also showed that kidney or Bright's disease is not usually painful, and it was held that where it is accompanied by pain of sufficient severity or frequent occurrence as to interfere with the applicant's ability to pursue his calling it becomes a factor in estimating the amount of the award.

ACCELERATION OF DISEASE BY STRAIN

Where the weight of the evidence showed that an applicant was injured in the handling of a car coupler; that as a result of that injury or the aggravation of his condition adhesions in the left inguinal region, by the strain in handling the coupler, he died within five days of his injury—that is to say, that the accidental injury contributed to his death, an award of compensation was affirmed. "Where a workman dies from a pre-existing disease or condition, if the disease or condition is aggravated or accelerated under circumstances which can be said to be accidental his death results from injury by accident. Acceleration or aggravation of a pre-existing disease is an injury caused by accident." Chicago & Alton R. Co. v. Industrial Commission, 310 Ill. 602, 142 N. E. 182.

EFFECT OF PROOF OF PRE-EXISTSNG HERNIA

The Georgia Court of Appeals holds, London Guarantee & Accident Co. v. Shockley, 122 S. E. 99, that while "in all claims for compensation for hernia resulting from injury by accident arising out of and in the course of the employee's employment, it must be definitely proved to the satisfaction of the Industrial Commission that the hernia did not exist prior to the accident for which compensation is claimed." Ga. Laws 1920, p. 170, 2, subd. (c); yet, where a claim is for a complete strangulated hernia, mere proof that prior to the accident from which the complete hernia arose, the claimant showed a possible sign of a partial hernia, but not attended by pain or reduced capacity for work, does not even authorize, much less demand, a finding that the hernia alleged to have resulted from the accident in question had previously existed.

EXPERT EVIDENCE AS TO HOW DECEASED RECEIVED INJURIES ADMISSIBLE IN MURDER CASES

In a wife murder case the theory of the state was that the fatal wounds were inflicted by repeated blows of a blunt instrument. The theory of the defendant was that they were caused by an accidental fall on stone steps. The body was found in the night time at the foot of the stone steps at the kitchen door of the defendant's home. She had suffered a slight contusion of her nose, a larger contusion on her left arm, two scalp wounds on the side of her head, a compound comminuted fracture of the skull at the back of the head, and the tissues below the place where the skull was crushed were reduced to pulp. The state introduced no witnesses who saw the wounds inflicted, and the defendant claimed that when they were inflicted he was in bed and asleep.

As against objections to expert opinions as to how the deceased received her injuries, the Kansas Supreme Court held, State v. Elftman, 226 Pac. 795, that the opinions of doctors who examined the wounds and the stone steps were admissible. The court said: "The data for the jury's inference lay in a field of knowledge scientific in character, most thoroughly apprehended by specialists. The trained professional mind has peculiar qualifications for observation and interpretation of such data. It was not possible to make experts of the jurors in the course of the ten day trial, and the only effective method of giving them the benefit of professional knowledge, training and skill, was to bring to their consideration conclusions in the form of opinions of those who were competent to express them. The true criterion for determining whether or not opinion evidence is admissible is correctly stated by Dean Wigmore to be: 'On this subject can a jury from this person receive appreciable help?" Wigmore on Evidence (2d Ed.), sec. 1923.

Further authority for admission of doctors' opinions in this case was found by the court in Kennedy v. People, 39 N. Y. 245, 256, where the question was as to the amount of force requisite to break deceased's skull; Clemons v. State, 48 Fla. 9, 37 South. 647, where the question was whether the fatal blow was struck with metallic knucks or some similar weapon, or with the naked fist; and Davis v. State, 38 Med. 15, where the question was whether fatal wounds were received by falling into a bin of a mill, or were inflicted by blows of a blunt instrument.

Intracranial Hemorrhage in the Newborn From the Obstetrician's Viewpoint*

MURRAY L. BRANDT, M.D.

New York

During 1924 there were 15,160 babies born in the Bronx. Of this number 629, or 4.1 per cent., were stillborn and 469, or 3.1 per cent., died during the first month of life, making a total of 1,098 potential lives lost during one year.

I therefore feel that the obstetrician should take a greater interest than he has in studying the cause of these deaths, so as to lower their frequency and by the recognition of early symptoms institute proper treatment.

Intracranial lesions play an important part in the production of this mortality. Accurate information concerning the incidence of these lesions, especially of tentorial lacerations, became available only after the adoption of Beneke's special technic of post-mortem examination of the skull. Older statistics are unreliable.

Reports of autopsies on infants stillborn and dying within a few days of birth up to 1919, revealed in 2,305 cases reported by various observers, 163 or seven per cent. having intracranial lesions, whereas 1,102 cases reported since 1919 by several clinics showed an incidence of twenty-nine per cent. of intracranial lesions. In the more recent statistics the percentage runs up to forty and fifty per cent. of all autopsies.

Intracranial lesions as a result of birth trauma are therefore common and are being discovered in ever increasing frequency, because they are being more carefully sought for. In a considerable percentage of autopsies, intracranial lesions, especially tentorial tears with slight or no hemorrhage, represent only accidental findings, proving that many infants survive, even though they have received definite intracephalic injury during birth.

In 1907 Seitz published his paper on brain hemorrhages in the newborn. This served to renew interest in this important subject, but it was not until 1910 that Beneke described the pathology and frequency of tentorial laceration. He described a method of opening the skull in the sagittal suture and carefully pulling the parietal bones down on either side. Rough manipulation results in injury to the underlying dura and indeed might cause a tear in the tentorium. Both hemispheres of the brain are then ablated and the tentorium laid free for inspection.

Most authorities agree that intracranial hemorrhages of clinical importance in the newborn are most often situated just above or just below the tentorium. The tentorium consists of an upper and a lower blade. The upper is the one more commonly torn, usually at its free edge.

There are three types of tentorial lacerations described: 1. A severe form in which the tear is through the free edge, often bilateral and through both blades of the tentorium. The edges are ragged, fringed and covered with thick coagula. Blood spreads upward and forward into the temporal fossa, often rising laterally over the occipital lobe. Occasionally the blood spreads downwards over the cerebellum passing into the spinal canal. 2. A milder form in which there is laceration of upper blade only and the hemorrhage is less severe. 3. A mild form which is most common, showing a small hematoma at the end of the falx or between the blades of the tentorium. This type is clinically often overlooked, as it may give rise to no symptoms and seldom results in death of the infant.

ETIOLOGY

Hugo Ehrenfest in America and Eardley Holland in England, maintain that trauma is the cause of intracranial hemorrhage in almost every case. Ehrenfest classifies the cause of this condition into: a, immediate causes; b, predisposing and contributory causes. Immediate causes are chiefly mechanical in nature. This origin is obvious in those cases of depression or fracture of the skull, either directly due to pressure from forceps blades, or to forcible traction along protruding portions of the rigid pelvic canal, such as the promontory, symphysis or exostoses. In cases where there is no evident obstruction to the passage of the fetal head, the mechanical cause is less apparent. Even though the fetal head is a fragile object, it displays remarkable qualities which enable it to resist injuries at the same time that it presents certain defects which dispose it to suffer them. The wonder is not at the relatively small number that suffer intracranial injuries but at the

*Read at a joint meeting of the Bronx Pediatric Society and the Bronx Gynecological Society, February 11, 1925.

Copyright, 1925, by A. R. Elliott Publishing Company.

large number that reach the world alive and uninjured.

During its passage the head is subjected to compression and therefore is in a state of stress. Cranial stress can be regarded as consisting of two elements. A general compression of the whole head and a simple longitudinal compression by opposite forces acting at the ends of the long diameter of engagement of the head in the pelvis. The outstanding feature of the fetal head is its ability to undergo changes in shape, or moulding, when subjected to stress. A certain amount of cranial stress occurs in every case, and in every labor there is a certain amount of moulding. When there is excessive cranial stress a dangerous degree of alteration in shape occurs. Bending of the cranial bones is resisted by the septa —i. e., the falx and the tentorium, and if the alteration in shape is too great, the septa tear. This tearing permits still greater alteration in shape and dangerous disturbance of intracranial contents occur.

Because of the belief that only evident mechanical factors caused intracranial injuries, it has generally been accepted that these injuries occurred only in difficult and instrumental deliveries. This view must be changed because it has been shown that serious intracranial injuries may occur in apparently normal spontaneous labors, especially if predisposing and contributory causes are present. These factors are asphyxia, prematurity and hemorrhagic disease of the newborn. Because of the general use of pituitrin, it must be emphasized that intracranial injuries may be caused by a quick compression of the fetal head of so short a duration, that even immediately after birth there will be no characteristics of prolonged compression, such as persistent overlapping of the cranial bones or a large caput. It should be remembered that intracranial injury may result from the forced passage of the fetal head through an undilated cervix and rigid vulvar ring.

A quick compression of the fetal head also occurs in multiparæ in whom the fetal head is not firmly engaged during the first stage of labor. These infants are frequently born in one or two pains as soon as cervical dilatation is complete. This rapid expulsion causes momentary compression and may cause severe intracranial injury.

The after coming head in breech delivery is frequently delivered rapidly and therefore is notoriously susceptible to intracranial injury. The strong pressure of the symphysis against the suboccipital region is the cause of tentorial laceration. It has been reported that in stillborn breech extracted infants, there were tentorial lacerations in seventy-five per cent., and it has been estimated that the aftercoming head is sixteen times more liable to suffer intracranial injury than in vertex presentation. In the newer method of breech extraction advocated by Potter this frequency is greatly lessened.

PREDISPOSING CAUSES

Prematurity.—In all series of cases of intracranial hemorrhage there is a high percentage of prematurity. This is ascribed to the fact that the bloodvessels and dura of the premature infant are very fragile due to their incomplete development. The premature infant is extremely vulnerable to the traumatisms of birth and in a large proportion of the fatal cases, labor is normal and spontaneous. Here again it must be emphasized that in spite of the fact that prematurity means a small baby and therefore less general compression, yet compression of the head may be rapid and of short duration, as might be caused by rigid soft parts in the birth canal.

Asphyxiation.—Asphyxiation was formerly regarded as an important cause of intracranial hemorrhage. This view has greatly changed since autopsies performed after Beneke's method have established the great frequency of tentorial laceration. This has led to a proper appreciation of the mechanical factors as a cause of intracranial injuries, many of which are not associated with hemorrhage. It is now believed that in many of the seemingly asphyxiated newborn infants, the asphyxia is the result rather than the cause of the intracranial lesion, and that efforts to overcome the asphyxia often exaggerate the effects of the intracranial lesion.

Most older statistics of the causes of infant mortality, within the first few days of life, fail to mention intracranial trauma. These deaths which are now known to be considerable, are included in those due to various obstetrical operations, but many, especially those subsequent to spontaneous labors, are classed as asphyxiation. Statistics regarding asphyxiation in the newborn are therefore misleading.

The etiological relationship of asphyxiation to intracranial lesions is limited to the belief that a congested vein is more likely than an empty one to rupture under pressure or strain. Asphyxia can only be regarded as a predisposing cause and occasionally as a contributory factor in so far as congestion may result in the extravasation of a larger amount of blood from an injured vein.

When a newborn infant is deeply asphyxiated, intracranial injury should be strongly suspected.

CONTRIBUTORY CAUSES

Hemorrhagic disease of the newborn.—In autopsies of cases of intracranial hemorrhage, it is occasionally noted that there are smaller and larger hemorrhages in the mucosæ and serosæ of the body. These were formerly considered as evidence of the asphyxia, which was believed responsible for the intracranial lesion. Most likely all the hemorrhages in such cases are due to a common cause, the hemorrhagic disease of the newborn. Of course intracranial trauma in the presence of hemorrhagic diseases of the newborn will result in a greater outpouring of blood from the injured vessel and result fatally sooner.

Manipulation during resuscitation.—In the Schultze method of resuscitation of the asphyxiated infant, the shoulders are grasped on either side and the head is fixed between the wrists. In the swinging there is frequently considerable lateral compression of the head. Such compression may cause tentorial laceration and since such an infant is asphyxiated and its vessels engorged, even a small tentorial injury may cause considerable extravasation of blood. In such cases the infant seems normal soon after resuscitation, but gradually presents signs of intracranial hemorrhage. All vigorous manipulations during resuscitation where the baby is swung or held head downward, will make a severe intracranial lesion of one that might have been mild or given no signs of its existence.

PROPHYLAXIS

It has been proved conclusively that in the presence of certain predisposing factors, especially of prematurity, the trauma of spontaneous normal labor may be sufficient to injure the intracranial structures, and that asphyxiation, brusque manipulation and hemorrhagic disease tend to exaggerate the effect even of minor lesions. Although this has lessened, it has not eliminated the responsibility of the obstetrician for such injuries. Certain obstetrical procedures undeniably prove disastrous to the infant. Disregard of certain details in the proper execution of obstetrical operations renders these procedures needlessly dangerous.

FORCEPS

The danger of high forceps is well known and every obstetrician of experience tries to evade this operation. The immediate mortality of this procedure has been calculated as between forty-three and fifty per cent. In forceps delivery with the fetal head firmly engaged or in midpelvis, statistical reports from large maternity services show a mortality varying from seven to twenty-seven per cent. These results are reported from obstetrical clinics, where the majority of the operations are in expert hands and are performed generally only for well defined indications. A reduction in the number of these injuries, which in part are unavoidable, can only be achieved by a limitation of the number of forceps applications.

Forceps must be applied for definite indications. When the operation is undertaken in the interest of the mother, the possible injury to the baby should be taken into account more seriously than is the prevailing custom. This applies to the obvious readiness of many to apply forceps because of assumed exhaustion of the patient, which usually is rather the impatience of the parturient woman or the weariness of the attendant.

When undertaken in the interest of the child, it must be remembered that prolonged compression of the head is less harmful to the infant than a difficult extraction. It is here that ironing out of the pelvic floor and episiotomy are useful to eliminate the possible danger of sudden and severe compression of the head by an unprepared and rigid vulvar ring. There is no doubt that the general practitioner underrates the difficulty of determining the necessity for a forceps extraction and of performing it properly with the least possible risk to the child. In many instances serious injury can be ascribed to defects in technic as follows: Too early application of the forceps, before the cervix has been eliminated as a barrier to extraction; the exact state of rotation of the head is not recognized, and the forceps are applied in the transverse diameter of the pelvis, but not as they should be, as closely as possible corresponding to the transverse diameters of the fetal head; during the process of extraction the direction of traction is not changed so as to correspond exactly to the sequence of flexion, rotation and extension required by the normal mechanism, as the head passes from one pelvic plane to the next. Failure to adhere to these requirements implies excessive and dangerous compression of the head in one or another direction.

The forceps should never be employed to overcome difficulties arising from a marked disproportion between the head and the pelvis. Traction should be made slowly with interruptions sufficient to permit the head to mould gradually. If the head is larger than normal, or the forceps blades cannot be employed along the shorter transverse diameter, the forceps handles necessarily will not be in close apposition. They must be steadied in their relative positions to avoid their compression during extraction.

AFTERCOMING HEAD

It is estimated that in breech labors under the management of the general practitioner, the mortality of the infant averages fifteen per cent. The clinical diagnosis of the cause of death is usually given as asphyxia, presumably due to compression of the cord between the pelvic wall and the aftercoming head. Postmortem studies have shown the actual causes of death to be spinal and intracranial injury, especially tentorial laceration in the majority of cases.

Correction of the malpresentation by external version before labor has started, is a measure of distinct value in prevention of birth injuries.

During the delivery it is important to eliminate both the cervix and the vulvar ring as a barrier to extraction of the head. This is accomplished normally by allowing the breech to progress spontaneously until the umbilicus reaches the vulva before the extraction of the infant is undertaken. This end is accomplished by the ironing out process of Potter. Slow and deliberate extraction of the head through a vagina and a vulva dilated after this method, occasionally aided by an episiotomy, will lessen the danger of intracranial injury without increasing the risk of asphyxiation. The application of forceps to the aftercoming head is a procedure that often facilitates the extraction of a head that might require undue traction and pressure from above to effect delivery.

PREMATURE LABOR

The high mortality of premature infants may be due to the trauma of birth rather than is customarily assumed, the immaturity of the newborn. Autopsies on all newborn infants bear evidence for the frequency of severe injuries after normal and quick labors in premature babies. The induction of premature labor as a method of dealing with minor pelvic contractions, is now rather generally discouraged because of the great loss of children in this procedure.

The vulnerability of the immature child renders it necessary also in spontaneous labors to avoid any severe or abrupt compression of the skull. Even a small dose of pituitrin, if it quickly forces the head through an incompletely dilated cervix or rigid vulvar ring may prove disastrous to an immature infant.

RESUSCITATION

Brusque manipulation must be avoided during the resuscitation of the asphyxiated newborn. Schultze's method of swinging should not be employed. Simpler procedures such as mouth to mouth insufflation, skin stimulation, hot and cold bath, intermittent traction on tongue, careful compression

of the thorax and insufflation of a few drops of aromatic spirits of ammonia, will prove sufficient if the asphyxia is not due to intracranial injury. This possibility must be kept in mind in cases of deep asphyxiation. Vigorous manipulations in such cases are prone to exaggerate the condition.

CONCLUSIONS

1. Intracranial lesions, mild and severe, develop in the course of both normal and abnormal labors.

2. Evidence of such injuries can be discovered at autopsy in approximately one half of all infants stillborn or dying within the first few days of life. But only in half of these cases is this injury the cause of death. In the other half such traumatic lesions, chiefly tentorial lacerations without or with slight hemorrhage, represent but incidental findings.

3. In a large number of cases today, intracranial parturitional injuries are overlooked.

4. Obstetrical routine should include a careful examination of the newborn and observation of his behavior during the first few days of life. Such a routine tends to reduce the number of unrecognized intracranial lesions and affords an opportunity for prompt therapeutic intervention.

5. Having learned to recognize these cases, we will make greater efforts to prevent their occurrence.

The Correct Conception of Thoracic Empyema and Its Rational Physiological Treatment

A. L. SORESI, M.D.
New York

(*Concluded from page* 465)

SPECIAL TECHNICAL POINTS. LINE OF INCISION AND DRAINAGE

Perfect drainage is most essential in treating empyema and the lowest point reached by the pleura might seem to be the most logical point to be selected for the incision. The pleura lines organs that form an angle (the costodiaphragmatic) as shown in Figs. 9, 10 and 11. Incision made in the lowest portion would have to go through thick muscular and fatty tissues and would actually not drain the pus. In fact, after pus has been present in the pleural cavity for some time the two leaves of the pleura lining the costodiaphragmatic angle become adherent and the space between the two leaves is occluded either by adhesions or fibrin deposited between them and there is danger of entering the peritoneal cavity. (Fig. 9.) Moreover, even if pus should escape freely when the incision is made, there would be danger that the diaphragm might later block the opening made in the pleura, after the bulk of the pus is evacuated, because the diaphragm which is low when the pleural cavity is full of pus raises up immediately after the pus is evacuated and obviously would block the very low opening made in the pleura, and cause a new collection of pus in the pleural cavity.

Incision must be made where the tissues above the pleura are thin, the intercostal space is wide, pus can be obtained freely, there is no danger of entering the peritoneal cavity. The incision recommended answers all these desiderata.

Incision close to the lower rib.—The incision must be made close to the upper edge of the lower rib in order to avoid lesion of the bloodvessels situated just below the lower edge of the upper rib. (Fig. 9.) Remember that hemorrhage from the intercostal vessels is very difficult to control and might be fatal, because the bloodvessels can bleed freely into the pleural cavity.

Incision of the pleura during inspiration.—Fig. 10 shows that the diaphragm is lowered during inspiration, so that in order to avoid injuring it, the incision of the pleura should be made when the diaphragm is lower, that is during inspiration.

Adhesions should not be broken.—Certain authors have recommended the breaking of all adhesions. Nothing is more dangerous than breaking the adhesions found in the pleural cavity. Breaking of adhesions opens numerous channels through which infection can be diffused. It will often cause a pulmonary fistula by tearing also some lung substance adherent to the adhesions. It makes complete restitutio ad integrum impossible, because in breaking the adhesions the epithelial lining is violently torn and must be replaced by connective tissue. Breaking of adhesions, therefore, is dangerous to life and prevents rapid and complete recovery. By using our cannula all adhesions break spontaneously and are reabsorbed, because the vacuum created in the pleural cavity actually forces the pus to break through any pocket in which it might have collected and compels the expanding lung to take its place. It is easily understood (Fig. 11) that even, when the pus is sacculated and our cannula is applied to the pleural cavity in a dependent position, the emptying of the lower pocket creating a vacuum and compelling the lung to expand, causes the breaking down of the adhesions that separate the different pockets and drains out all the pus contained in the pleural cavity. We had a striking illustration of this in a case in which clinically the pus appeared to be abundant and after opening the pleural cavity only a comparatively small quantity of pus was obtained. In the afternoon the patient had a sudden strange sensation in his chest and dyspnea: pus filled rapidly a six ounce bottle connected with the cannula and overflowed. As an x ray examination of the patient had not been made, we can only surmise that we had to deal with a case of sacculated empyema, as represented in Fig. 11, a large pocket of pus breaking a few hours after the pleural cavity had been

opened. The recovery was complete and very rapid, twelve days.

ACTION OF AUTHOR'S CANNULA

The physiopathologicomechanical problems that present themselves in treating empyema are ideally solved by our cannula. Practical experience has demonstrated that our cannula will positively drain all the pus that is found in the pleural cavity, whether the pus is thin or thick, free or closed up in small or large pockets; compel the lung to expand gradually and progressively; not cause any shock, deformity or any other immediate or late complication; reduce trauma to a negligible minimum; allow the patient a maximum of comfort and confidence during and after the operation; shorten the time of treatment; make possible operation even in moribund cases with great possibilities of saving life, and make possible and easy the cure of double empyema.

FIG. 14.—Patient twenty-four years of age. Streptococcus empyema following influenza. Patient was in very poor general condition, but notwithstanding these handicaps was cured in less than three weeks. See Figs. 15 and 16. Picture shows right pleural cavity filled, with great amount of fluid and heart shadow displaced to the left.

Simultaneous drainage and expansion of lung.—The drainage of the pus and expansion of the lung take place simultaneously after the application of the our cannula. Drainage does positively and continuously take place for the following reasons: pus or membranes are easily passed through the channel formed by the cannula, which is much larger than the opening obtained even after extensive rib resection when rubber tubing or other drainage material is used. In fact, the cannula is made of extremely thin metal which occupies little space; its channel cannot be obstructed or narrowed at any point or under any circumstances, because obviously it cannot be compressed and its oval shape allows the exit of large membranes. The large size of the channel established by the cannula between the pleural cavity and the outside, although enormously wide, favors lung expansion, because it is provided with a positive valve which allows the exit of the pus but does not allow air to enter the pleural cavity, realizing airtight closure and drainage of the pleural cavity at the same time.

This is perhaps the most striking and valuable feature of the cannula. Indeed, it is seen (Fig. 12, A, B) that the valve can close the cannula completely, making it airtight, so that, when the patient inhales, the atmospheric pressure will push the valve against the edges of the opening of the cannula and completely prevent the entrance of air into the pleural cavity; while, when the patient exhales, the valve is raised up and part of the pus and any air contained in the pleural cavity will escape outside. Thus really effective automatic elimination of all the pus with progressive gradual expansion of the lung, and the rapid and positive cures obtained, even in cases of double empyema, can be understood. On opening the pleura some pus escapes through the incised tissues and air enters the pleural cavity, so that the pleural cavity is filled by pus, air and the retracted lung.

We rapidly apply the cannula. What happens? The opened pleural cavity becomes again a closed cavity to the effects of intrathoracic pressure, because no air can enter it, so that the organs of the mediastinum, the other lung and the diaphragm begin immediately to functionate again as before the establishment of the empyema, that is in a perfectly physiological manner, notwithstanding the fact that the pleural cavity of the affected side of the thorax is still pathological, because it contains pus, air and the corresponding lung is retracted. The condition just described and created by the application of the cannula is an important factor in the rapid complete recovery of the patient, because it is evident that the more normal, that is, the more nearly physiological are the conditions of the organs just mentioned and the function of which is most intimately associated and affected by the function of the diseased side of the thorax, the more rapid and sure will be the complete reestablishment of the physiological conditions of the entire thorax, which means complete recovery of the patient.

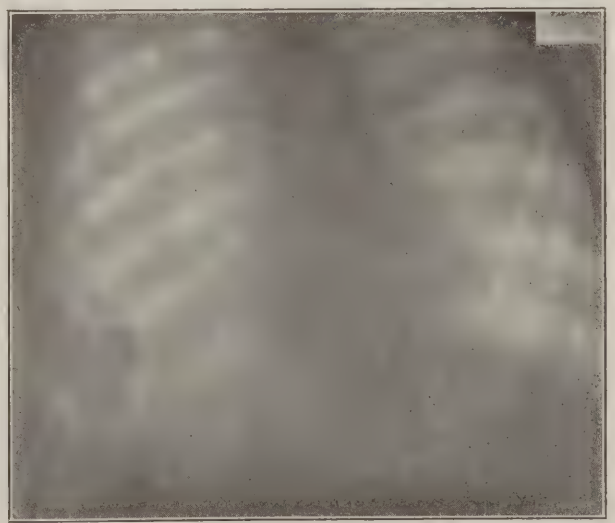

FIG. 15.—Same patient six days after operation. Right pleural cavity filled somewhat in lower third suggesting thickening of pleura and slight amount of fluid.

The application of the cannula has therefore created the following condition: the whole thorax is a closed cavity to the effect of intrathoracic pressure, pus and air are present in the affected side of the

thorax, fill the pleural cavity, compress the lung and to a certain extent the organs of the mediastinum, the other lung, the diaphragm. The patient breathes, and, even supposing that the lung of the affected side be adherent to the parietal pleura and not easily distended, at each respiration some pus and some air will, and actually do, escape through the cannula,

Fig. 16.—Same patient nine days later. X ray report (Dr. Van Winkle) right lung filled is practically clear throughout. On this day the cannula was removed and patient discharged six days later.

because the healthy lung expands, and in so doing dislodges the contents of the neighboring pleural cavity, that is, the pus first and then the air contained in it, which escape through the cannula. Consequently at each respiration we can see a certain amount of pus come through the cannula.

That the pus at the beginning is expelled by the action of the healthy lung and the diaphragm seems to us logical, because in many cases the affected lung has been compressed for such a long time that it seems illogical to think that it will begin to expand again after the application of the cannula, while the pleural cavity is still full and under the pressure caused by the pus and the air, and the fact that there is always some displacement of the healthy organs of the other side of the thorax and of the diaphragm. These organs which can expand freely will do so: as soon as the action of the valve of the cannula allows. Also the fact that pus does not come out in a continuous stream, but in small quantities at each expiration, proves our contention. We stated that pus is expelled first and then the air. This is a fact of great importance. We also stated that one of the most important elements in the physiological treatment of empyema is the early gradual progressive expansion of the lung, and we think that no one can challenge this statement. No other apparatus or instrument or method of treating empyema allows or favors, and, we could say, almost compels such an automatic, gradual progressive expansion of the lung. Indeed, when we open the pleural cavity, we allow air to enter it; after we have applied the cannula no more air can enter the pleural cavity, so that the affected lung, the organs of the mediastinum, the other lung, and the diaphragm are compressed, immediately after the application of the cannula, by the pus still present in the diseased pleural cavity and by the air that entered it during the operation.

We have seen that the diaphragm, the healthy lung, the mediastinum, tend to reassume their normal positions and functions and in so doing dislodge the pus which escapes through the cannula during expiration. When all these organs have reassumed their normal positions and functions, the diseased pleural cavity still contains pus and air. The continuous respiratory movements will alternatively compress and relax the diseased pleural cavity, so that at each compression pus and air will escape through the cannula, which, however, will not allow any air or pus to reenter the pleural cavity, because the valve completely closes the cannula. We have, therefore, the following condition: a thorax which is closed during inspiration, and opens during each expiration, allowing a certain amount of pus and air to be expelled through the cannula, so that in the diseased pleura a certain amount of vacuum takes place. As *natura abhorrit a vacuo,* the vacuum so created must be filled by some organs. At first the depressed diaphragm, the dislodged mediastinum and the healthy lung reassume their normal position, later they might even be dislodged towards the affected side of the thorax. In doing so, however, there will be a kind of drawing on the contracted lung, which will also be forced to expand in order to fill the vacuum created by the expelled pus and air contained in the pleural cavity, until the lung is com-

Fig. 17.—Boy, eight years of age. Pneumococcus empyema. Right pleural cavity filled, heart displaced to left. The pleural cavity was filled with thick pus and membranes. Cannula was removed by mistake by house surgeon only six days after operation.

pletely expanded and has filled again the pleural cavity. It is easily understood how the lung is gently forced to expand, and pus will be evacuated, no matter how thick or whether it is incisted in large or small pockets. The air that has entered the pleural cavity during the operation acts as a cushion on

which the affected lung can rest; is lighter than the pus and so the pus will be eliminated first, through the cannula put in a low section of the thorax; but air is elastic so that the vacuum created at each respiration after the greater amount of pus has been expelled, will not expel a great quantity of air, but a quantity that will be proportionate to the amount of expansion that the lung is able to obtain. The expansion of the lung is consequently regulated automatically by the lung itself, according to its possibilities, and not forced as it would be if some one from outside would try to create a vacuum, which procedure would be extremely dangerous.

It is clear now why we are pleased that air enters the pleural cavity during the operation, and why we do not try to evacuate any pus at the time of the operation, but allow the pus to come out spontaneously after the application of the valve. The explanation given above makes it easy to understand why patients do not collapse but feel greatly relieved immediately after the application of the cannula. Some patients feel so well they even ask to walk back to their room. The explanations given above show also why we deprecate so strongly the breaking of any adhesions, even if they should have divided the pleural cavity in various compartments as shown in Fig. 11, forming a sacculated empyema. Indeed, even if the pus was closed up by strong adhesions, the vacuum created by the continuous repeated expirations would break these adhesions because the pus would be compressed on all sides by the expanding lungs, and diaphragm. No adhesions could withstand the continuous bulging caused by the vacuum created by the respiratory movements, which are repeated without interruption about twenty or more times each minute, day and night. If *gutta cavat lapidem,* certainly the continuous bulging of the membrane closing up pus will break and allow the pus to escape and favor early cure.

CRITICAL REVIEW OF OTHER METHODS OF TREATMENT

The preceding considerations make lengthy criticism unnecessary. The methods that keep open the pleural cavity prevent expansion of the lung, whether they attempt to sterilize the pleural cavity or simply drain it. The methods resorting to aspiration of pus without opening the pleural cavity, leave pus in the pleural cavity and do not actually compel the lung to expand as it would appear to do. Indeed, the only manner in which the lung could be forced to expand with the pleural cavity closed, would be to actually remove all the pus and create a vacuum, which would be filled by the lung. It is only necessary to mention that if a vacuum was created the inflamed pleura would bleed profusely, to demonstrate that such a vacuum with consequent lung expansion is not actually created. The methods which try to create a valve with living tissues fail to do so; at the best they only obtain an imperfect and temporary valvular action. That all the methods fail in some respect is proved by the fact that the earliest cure is obtained after six to seven weeks in the most favorable cases, the average being from two to three months, when chronic empyema or other complications do not set in to delay the cure indefinitely or cause death.

The amount of pus and the length of time during which pus is drained from the pleural cavity, constitute the most convincing criticism, when patients treated by the method described are compared with patients treated by any other method. In patients treated by our method, the amount of pus decreases so rapidly that a few hours after the application of the cannula only a few drops are drained. When any other method is applied, the amount of pus is enormous days and weeks after. How can we explain this difference? There is only one possible explanation: the means used to treat the pleural cavity do actually cause pus production, thus delaying

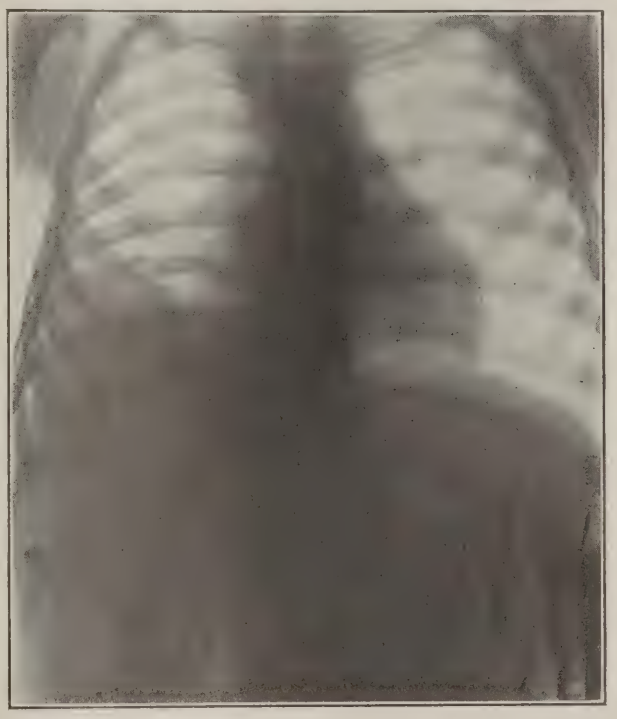

FIG. 18.—Shows how lung has expanded in only six days. Cannula was not replaced; only four paraffinated threads were used for drainage (threads secured by safety pin). Patient discharged cured twelve days after operation.

radical cure, while our method prevents pus production, thus hastening radical cure.

CONCLUSIONS

The filling of the pleural cavity with secretions, whether sterile or purulent, always represents the most valuable means of defense of the organism. This means of defense must not be hampered by early radical intervention. Secretions collected in the pleural cavity must be evacuated only when and after they have played their defensive rôle, and the *causa prima* is removed or its activity has ceased. Small quantities, however, should be removed for diagnostic purpose and to relieve pressure. The direct treatment of empyema must be based on expansion of the lung and simultaneous evacuation of the pus. The treatment of thoracic empyema, like any other pathological condition, requires some surgical skill and clinical experience. A direct method of treatment has been described which obtains simultaneous expansion of the lung and positive drainage; renders the treatment painless; shortens its duration from a few days to an average of two weeks, and prevents the complications commonly observed in cases of thoracic empyema.

Effusions Into the Knee Joint and Housemaid's Knee

ETHAN H. SMITH, M.D.

San Francisco, Cal.

In no class of surgical cases commonly occurring is there less unity of opinion in the world of surgery today than in those cases involving the knee joint, in which there is a collection of fluid within the joint cavity. The common expression by which many of the laity understand this condition, is summed up in the expression, "water on the knee." This is a most unfortunate designation, for the reason that it has its influence on the mind of the medical profession and surgery itself. It has led to a gross misunderstanding of diseases, and injuries affecting the knee joint. To one person water on the knee does not convey to his mind anything serious. To another it is a matter of grave apprehension. In the rank and file of the profession there is no rational plan for handling these cases.

The fluid which may be in the knee joint may be serous, purulent, bloody or contained within the meshes of an edematous synovial membrane. The presence of a serous fluid may be due to trauma, infection from within the body through the blood stream, or irritation from some unusual exertion. Pus is always due to infection from some of the pathogenic organisms. It may follow trauma, or an infection from internal sources. Blood, or a bloody fluid, comes from three sources. First, and most frequent, severe trauma; second, infection from some of the hemolytic organisms; third, hemophilia.

The pneumococcus, and kindred organism—diplococci—at times invade the knee joint and cause a collection of serous fluid. Pus is not often associated with the condition. There may be no pain, no swelling of any appreciable consequence, no redness or rise in temperature. The synovial pouches of the knee joint will be distended by fluid within one or two days' time. Some time both knees will be simultaneously involved. Eventually pain will be present due to pressure within the overdistended tissues surrounding the joint. Seldom can we recover the infecting organism in these cases. If the effusion is detected within the first forty-eight hours, a culture will sometimes reveal the organism responsible for the condition.

I once removed fluid from the left knee of a young woman. She had known that something was wrong with her knee for nearly three weeks. She had no systemic disturbance whatever and while not a very robust woman, she had never been confined to bed by illness, except at the birth of her baby one year before the condition of the knee developed. Careful examination failed to detect disease elsewhere in her body. Her teeth were good, her tonsils negative. No evidence of a pathological condition existed in the entire abdominal region. The fluid when drawn from the knee joint was dark amber, but wholly translucent. Cultures of this fluid were negative. Within forty-eight hours her right knee was greatly distended with fluid. This fluid was very pale amber color. Cultures of this fluid resulted in pure growth of the lanceolatus of Frankel. This culture was of such vitality that subcultures were made from it for four months before being exhausted.

The gonococcus is responsible for many acute collections of pus in the cavity of the knee joint. Other infections rarely produce acute filling of the joint with pus, without an external injury communicating with the joint.

Tuberculosis of the synovial membrane, that has not extended to the other structures of the joint, may produce, first, a serous collection of fluid, which if not promptly removed will become purulent from mixed infection. Tuberculous effusions will occur again and again, until the diseased synovial membrane is completely removed. In 1910, in the San Francisco County Hospital, I had a man about fifty years of age, who gave a history of having severely wrenched his left knee, in leaping over a ditch, twenty-seven years before. His knee hurt him so badly at the time that he was laid up for about two weeks. Afterwards, although he suffered severely from pain in the knee, he went about his work as a laborer. He was large and muscular, but lean and except for the injury to his knee his health had been exceptionally good. He became a stoker on a steamship.

About ten years after the original injury he was in a hospital in San Francisco because of trouble with his knee. He said that at this time it was operated on twice, but he could not tell what was done at either time. There was no scar, or mark of a cutting operation about his knee. He said he was away from work for about four months.

In about seventeen years he again came to the San Francisco County Hospital and was placed in my service. Aside from his knee his general condition was good. He had led rather a rough life, but denied any venereal disease, or any illness that had confined him to bed aside from the knee. There was considerable fluid in the knee. There was also considerable thickening of the synovial membrane, both above and below the patella. The fluid from the knee was cultured. A growth took place in the culture medium, which responded to all of the tests for tuberculous bacilli. Guineapig test was positive for tuberculosis. I opened the joint and made an extensive dissection of all the diseased synovial membrane that could be found. There was no sign of pus, or erosion of any of the structures of the joint. The knee healed kindly, and in about three months the patient returned to his job as a stoker. I never saw, or heard of him again.

After an accident in which the knee is bruised and severely injured, without any penetrating wound an immediate filling of the joint with fluid, or filling within twenty-four hours, is always due to a hemorrhage into the joint. If the blood is not promptly removed, one of three things will happen. Secondary infection, with abscess, rapid organization of the blood clot with many adhesions of the overlaying soft structure, or a chronic involvement of the

joint with broken down blood clot, which will result in delaying convalescence, and possibly permanent crippling.

A history of hemophilia will give sufficient data on which to base a diagnosis of hemorrhage into the knee joint in such a patient. I shall make no comment on the handling of such a case. My own experience has taught me that proper handling of these cases has never been learned.

Serous fluid and blood due to trauma should be promptly removed from the knee joint by aspiration. This should be done under full aseptic precaution. No antiseptic fluid should be injected into such a joint. The best point at which to enter the synovial pouch, is just above the patella and just below the margin of the outer border of the quadriceps tendon. An assistant must make careful pressure above and below the patella, so as to bring the fluid into one common collection, just above the patella, during the aspiration.

The knee should then be encased in a light plaster of Paris dressing, over good absorbent cotton (never sheet wadding). A felt pad with a hole in it should be placed over the front of the cotton to prevent pressure on the patella. The plaster should extend from two inches above the ankle joint, to the gluteal fold, with the knee a trifle flexed. A short plaster of Paris dressing, just encasing the knee, is an evil thing under any circumstances. Moleskin plaster applied to the leg on each side and reflected over the bottom of the cast is essential to hold the cast from slipping down. Any attempt to apply the cast tight enough to prevent slipping when the patient stands, is exceedingly bad practice. Slit the plaster in front throughout its entire length at once.

As housemaid's knee often follows trauma, either from a blow over the prepatellar bursa, or irritation from being on the knees at some occupation I choose at this time to mention it in this article. In a true case of prepatellar bursitis the treatment should be radical. Conservatism has no place in this condition, providing the diagnosis is correct. If there is acute suppuration, the pouch should be freely opened, and drained from the most dependent point. The incision should not be made over the central portion of the bursa, but transversely, and at the lowest point, which will communicate with the bursa. As soon as the pus has cleared up a transverse curvilinear incision with the concavity upward, should be made so as to go just below the bursa. A flap should be turned upward, and the bursa dissected out, care being taken not to tear it into shreds, but to remove it in one mass. If this is not done a chronic condition will supervene, and recur with acute outbreaks. The knee joint may become involved. To temporize with one of these cases means depriving the patient of the chance to work until the infected bursa is removed. Aspirating a housemaid's knee is absolute folly. Sticking a needle into a cellular mass of edematous tissue is a quite successful way of infecting the whole mass, and productive of no good whatever. In the absence of acute pus dissect out the bursa at once. Do not ligate vessels with catgut. Either stop them with a silkwormgut suture, brought through the skin, and tied over a pledget of gauze, or stop them by application of a hemostat applied for a few minutes. Close the wound with a silkwormgut suture, without drainage in the absence of pus. Opening into a bursa at its central portion, and attempting to wash out with an antiseptic is dangerous practice. I have seen a sinus running halfway around the knee, together with a slough larger than a nickel around the original puncture following such a procedure.

I have seen suppuration continue for months following aspiration, and incision, without removal of the bursa. Careful and complete dissection of the bursa means one hundred per cent. cure, if done promptly.

528 Flood Building.

Vasomotor Rhinitis

With a Report of Eight Cases Reacting to Orris Root

E. M. ROBINSON, M.D.
Brooklyn

The symptoms of vasomotor rhinitis are practically the same as those of acute simple rhinitis, or ordinary coryza. In both, there is a sudden access of sneezing, with fullness of the nose and throat, and an abundant discharge of watery mucus. The eyes become congested, the lids are swollen and red, lacrimation is increased, and there is a mild photophobia. The external nose is also swollen and red. Taste and smell are impaired and because of this the appetite also suffers.

From the nasal mucous membrane, the engorgment spreads to the accessory sinuses of the nose, to the pharynx, soft palate and uvula, the result being headache, difficulty in swallowing, itching and tickling of the roof of the mouth and an irritating uvular cough.

But while vasomotor rhinitis and acute simple rhinitis are symptomatically identical, they differ completely in their etiology; and due to the difference in their causative factors, there is also a great difference in their duration. Acute simple rhinitis is caused by an infection of the nasal mucous membrane, brought on by exposure to cold. Its duration is only about one week or ten days, while vasomotor rhinitis, according to its causes, may last for weeks, months, or all the year round, as the socalled perennial vasomotor rhinitis.

VARIETIES OF VASOMOTOR RHINITIS

Vasomotor rhinitis which is caused by the pollens of plants, the socalled hay fever or pollinosis, constitutes by far the largest group of cases. It is

well known that over a million persons in the United States, or about one in every hundred, suffer from hay fever.

In this group of cases, the duration of symptoms coincides with the duration of the pollination of the plant or plants to which these subjects are sensitive. So that a small number of persons, about one per cent. of all hay fever victims, who are sensitive to tree pollens, such as maple, willow, oak and horse chestnut, will have their attacks of vasomotor rhinitis from about the middle of March to about the middle of April, because that is the time when trees pollinate. Another group of patients, about seven per cent., who are sensitive to grass pollens, such as June grass, timothy, orchard grass and red top, will suffer from the beginning of May to the end of July; and the remainder, who are sensitive mainly to ragweeds, will have their pollinosis from about the middle of August to the middle of October. The cases caused by pollens are called seasonal vasomotor rhinitis.

Then there is a group of patients who complain of hay fever symptoms throughout the year, the so-called perennial hay fever. In this group there are a number of cases that are allergic, and the main protein to which these patients are sensitive is the protein contained in orris root.

In a series of twenty cases, which I have treated, there were eleven nonallergic, that is, not reacting to any protein, and nine allergic. In the allergic cases, there was only one patient who reacted to goose feathers. In the rest of the cases the vasomotor rhinitis was caused by inhaling the protein of orris root.

Orris root is a native of Italy, mainly near Florence, where it is dug up in the spring and after it is cleaned of its rootlets and outer layer, it is dried and ready for export. On account of its fragrance, it is pulverized and used in a good many cosmetics, such as face powders, perfumes, shampoos and soaps.

The causes of nonallergic vasomotor rhinitis are not well known. Some assert that it is due to some endocrine imbalance, but this has not been definitely proved. Others, again, think that all cases of vasomotor rhinitis are due to protein hypersensitivity, but in many cases the isolation of the responsible protein has not been successful.

TREATMENT

If it were possible to remove the patient from his specific protein or remove the protein from the patient, this would be the ideal treatment; no pollens, no hay fever; or no inhalation of other proteins, to which the patient is sensitive, no symptoms; but as a rule, this is impossible.

Pollens, in season, are in the air in great quantities, especially those light pollens of the grasses and ragweeds, which are borne even by an ordinary wind for miles and miles. And there are only a few places which are pollen free, such as the ocean and high altitudes.

The same thing can be said about orris root. While not every one uses cosmetics, yet they are so universally used, especially face powder, that the air is almost full of it and, therefore, we have to resort to desensitization treatment.

Desensitization is carried out in the following manner: An extract is made of the pollen or other protein to which the particular patient is sensitive; that is, if he is sensitive to the pollen of timothy grass, we make an extract of that pollen and inject it into him, beginning with very minute doses, which are gradually increased, so that at the end of the treatment the patient is desensitized. The same process is used with orris root, and in all other protein desensitization.

CASE HISTORIES

Case I.—Miss S. C., aged twenty-one, a schoolteacher, was sent to me by a well known rhinologist, on November 20, 1922, as a severe case of vasomotor rhinitis of two years' duration. She had visited almost every rhinologist in the city and was operated on for some pathological condition in her nose, but without relief. The last rhinologist whom she visited suggested protein tests. On being tested, she gave a strong reaction to orris root and we decided to desensitize her. On account of her extreme sensitivity, the desensitization took almost a year, but she has been completely free from symptoms since her tenth injection, and is perfectly well up to the present time.

Case II.—Miss S. K., aged seventeen, a student at Hunter College, came to me on October 25, 1923. She had been suffering from vasomotor rhinitis for a number of years, being considerably worse during the months of June and July. On being tested she reacted very strongly to orris root and also to two grass pollens. She was desensitized for orris root and also for the grass pollens. She has been perfectly well since.

Case III—C. M., aged twenty-two, milliner, came to me on April 24, 1923, suffering from perennial vasomotor rhinitis of a few years' duration. On testing her, I found that she reacted to orris root for which I desensitized her. She was greatly improved for about four months, after which time her symptoms returned. The peculiarity about this case is that whenever the patient is in the mountains, no matter for how long a time, she feels perfectly well.

Case IV.—Miss L. B., aged twenty, a salesgirl, was referred to me by a well known rhinologist to be tested for proteins, as she had been suffering for about a year and a half from the perennial type of vasomotor rhinitis, stating that there was no pathology of any kind to be found in her nose. She reacted very strongly to orris root. On June 8th, I completed her treatment and she has been well since.

Case V.—Mr. H. S., aged thirty-three, a printer, came to me on May 31, 1924, complaining of perennial vasomotor rhinitis, which had lasted for a number of years. He showed a pronounced reaction to orris root, but unfortunately I was unable to desensitize him, as the extract of orris root, prepared by a well known firm, happened to contain an excess of creosol, which is used as a preservative; and this inflamed his hand to such an extent that he was unable to work for about a week. Needless to say that he refused the continuation of further desensitization.

Case VI.—H. G., aged thirty-five, a manufacturer, came to me on May 25, 1924. He had suffered from hay fever of the autumnal type for the last seven years, with occasional hay fever like attacks all the year round. On testing him, he showed strong reactions to the pollens of both the giant and dwarf ragweeds and also to the pollens of sunflower. He was desensitized by a mixture of these pollens and he felt quite well during the entire hay fever season. After the hay fever season was over, I tested him for other proteins and I found that he was very strongly sensitive to orris root, for which I am now completing his desensitization. He has been practically free from all symptoms since his sixth injection.

Case VII.—Miss L. S., aged twenty, a dressmaker, came to me on July 31, 1924, with a history of suffering from the perennial type of vasomotor rhinitis for a number of years. Orris root was the only protein she reacted to and very strongly at that. I completed her desensitization November 21st and she has been absolutely well since the beginning of her desensitization, in spite of the fact that she has been using face powder.

Case VIII.—Mrs. R. H., aged twenty-eight, a housewife, came to me on July 10, 1924. She had suffered from vasomotor rhinitis for the last two years. On being tested she gave a very marked reaction to orris root. I have just completed her desensitization, but Mrs. H. has been free after her tenth injection, excepting a mild attack, which was caused by using a shampoo which contained a good deal of orris root. At present her reaction to orris root is negative.

Purulent Pericarditis in Childhood*

ALFRED C. WOOD, M.D.
and WILLIAM N. BRADLEY, M.D.
Philadelphia, Pa.

(*Concluded from page* 484)

CASE REPORT

History of Case.—March 25, 1923. The patient was a male, white, four years and nine months of age. Ten days previously, following what, according to description, was rubeola, the child had become worse, and suffered from high fever, cough and pain in the abdomen and back. The physician in charge had made a diagnosis of bronchopneumonia.

At the first visit, March 25, 1923, the patient's condition was as follows: He complained of cough, and pain in the epigastrium. There was fullness of the latter. Temperature 102.4°. No vomiting; bowels constipated; soreness in abdomen and back; throat reddened; postnasal mucopus; tonsils large; no evidence of ear disease; no desquamation; fine râles in the left lung posteriorly; urine contained albumin. A diagnosis of bronchopneumonia of left apex was made and treatment instituted accordingly. The next day the temperature had fallen to 99° and the general condition was somewhat improved. For several days the child's condition remained the same. Then a rise in temperature was noted in the afternoon (100-101°) with constant complaint of persistent pain and tenderness in the epigastric region. The heart sounds were clear, the apex visible and palpable in normal position; no increase of cardiac dullness noted. Of particular interest was the sighing respiration of the child.

On April 6th, his general condition became distinctly worse and we concluded that an empyema was present and advised admission to the hospital for x ray and exploration.

Hospital Notes.—L. P., aged four years, nine months, was admitted to the Howard Hospital April 8, 1923.

Chief complaint: Epigastric pain, swelling under eyes and distention of the abdomen.

Family history: Father and mother living and well. He was the only child.

Examination: Eyes, pupils equal, reacting regularly to light and accommodation; no ocular palsies; no exophthalmos. Ears, no evidence of disease. Mouth, tongue slightly coated; teeth normal for age. Pharynx congested; tonsils not cryptic; subtonsillar glands merely palpable; no mastoid tenderness; no edema of skin over mastoid. Some edema of face. Neck, no abnormalties. Chest, expansion good and equal, no gross deformity. Lungs, percussion note resonant, though some slight impairment at left apex. Breath sounds bronchovesicular at right apex; somewhat prolonged posteriorly; no râles. Voice sounds normal. No bulging of interspaces. Heart, a visible, rather diffuse cardiac impulse, which was easily palpable and was simultaneous with systole. There were no audible murmurs, no arrhythmia, no displacement; heart muscle tone was good. Abdomen, somewhat distended. There were no areas of tenderness, or palpable masses. A movable dullness was present in the flanks with a tympanic area in the midline, probably due to some fluid. The peristalsis was normal. There was no hernia present. There was perhaps a slight edema in the lumbar region. Extremities, no edema, no gross abnormality. Temperature, 103°.

April 9th: Dullness over left apex in front and laterally; posteriorly, the note was hyperresonant. Abdomen distended, but not tender or rigid. Dullness in both flanks, disappearing when the child was turned on the side. Apparently some peritoneal effusion. Urine contained a trace of albumin and a few hyaline casts. Blood count was as follows: Erythrocytes 4,120,000, leucocytes 15,400, hemoglo-

*Read before the Section on Pediatrics of the Medical Society of the State of Pennsylvania, October 7, 1924.

bin 80 per cent., polymorphonuclears 50 per cent., lymphocytes 50 per cent. X ray showed effusion of left chest, which was totally opaque up to the level of the third rib posteriorly.

April 10th: Dullness over lower left lung posteriorly.

April 11th: Dullness over left lung increasing.

April 12th: Exploring needle inserted in the seventh interspace, postaxillary line, and sixty c.c. of serum withdrawn, without anesthesia. Light ether anesthesia was then induced. Exploring needle inserted in second interspace just outside of nipple line drew pus. Incision; two rubber tubes introduced for drainage between second and third rib.

April 15th: No drainage. Upper tube removed; lower tube shortened.

April 16th: Tube shortened; only suspicion of drainage, but general condition not improved. Pus from chest was sterile after ninety-six hours. Direct smear showed many pus cells and a few streptococci. Culture grew streptococci, nonhemolytic, and staphylococcus aureus, probably contaminated.

April 17: Tube removed; exploring needle inserted perpendicularly through wound and 140 c.c. of pus were withdrawn. The position of the needle, the depth to which it was inserted and the fact that each heart beat could be felt by the hand holding the syringe led to the diagnosis of pus in the pericardial sac. Further operation was postponed as permission of the parents had not been obtained for a major operation.

April 19th: The x ray showed "a decided decrease in size of area reported eleven days ago. While it is true that this shadow has the waterbottle shape of a pericarditis with effusion, the cardiohepatic angle is not obliterated and the density of the shadow is not uniform, it being more dense in the left than in the right. There is a definite increase in width in the mediastinal shadow which extends up above the level of the clavicle. This mediastinal shadow could be caused by glandular enlargement."

April 20th: Impaired resonance, one finger's breadth to right of sternum reaching up to clavicle; apex beat not visible. Heart sounds muffled, mitral sounds heard best at fourth interspace, one cm. within nipple line. Aortic sounds extremely muffled, no murmurs heard. No difference in the measurement of each side at nipple line.

April 21st: Ether anesthesia. Incision through site of old wound after antiseptic preparation and tincture of iodine application. The left third rib was exposed in the nipple line by transverse incision, and about one and one half inches of bone resected subperiosteally. This revealed a bulging tumefaction, which upon being opened discharged about two hundred and fifty c.c. of yellow pus. The cavity was irrigated with warm saline solution. The examining finger passed through the incision came in immediate contact with the heart. No drainage was inserted, and the wound was not sutured, being left open to insure free drainage. The general condition of the child remained satisfactory through the operation. The respiration at the time of opening the pericardial sac was 36; after evacuation of the pus the respiration was 56. No cough or other signs of pleural irritation occurred. X ray examination after operation showed a marked diminution in the size and density of the shadow. The upper mediastinal shadow still persisted.

April 24th: The drainage had become scant and it was found that the wound had become partly closed. It was freely opened with the finger and a considerable amount of yellowish pus evacuated. The wound was irrigated with Dakin's solution and dressings reapplied. The general condition remained unchanged.

April 25th: The discharge was still scant. The wound was again divulsed and a drainage tube inserted, through which a free discharge of pus was evacuated. The sac was again irrigated with Dakin's solution.

April 26th: Free thin purulent discharge, the tube was reintroduced and Dakin's irrigation repeated.

April 30th: Gradual lessening of discharge. General condition good.

May 1st: X ray report was: "The heart and mediastinal tissues are retracted to the left so much that the right border of the heart does not project beyond the right sternal border. The pericardial shadow is probably less dense than it was."

May 3d: Practically no discharge. General condition improved.

May 6th: Wound healed over. Condition very good.

May 12th: Pulse 100, full, regular. Heart sounds normal in quality and intensity. Heart dullness normal. A few moist râles at base of left lung. Slight impairment at left base; thickened pleura.

SURGICAL CONSIDERATIONS

The surgery of the pericardium naturally falls under two great heads—traumatic and elective.

The traumatic is wholly emergency and the operator is generally confronted with a more or less serious proposition, depending upon the damage done to the heart muscle and contiguous structures, coincident with the wounding of the pericardium. The degree of uncontrolled hemorrhage, together with that already sustained, generally decides the issue. Simple suture, preferably through the original wound, enlarged, if necessary, with the evacuation of any retained blood clot within the pericardium together with drainage (flexible preferred) constitutes the proper surgical treatment.

The elective surgery covers a much wider field and much remains to be said. A late diagnosis being generally the case, the operative procedure is necessarily fraught with much danger and this danger is in direct ratio to the time of the diagnosis and the complications present. Pericardiotomy in a strong well child assumes no graver aspect than thoracoplasty would in the same subject, and in both it might be said that the operative risk is practically nil. But in the highly septic, moribund patient the doors of heaven are gaping widely, ready to receive your patient. Early diagnosis of pericarditis with effusion, either serous or purulent, is the only factor that will cut the sixty per cent. mortality. All work done must be rapid, nontraumatizing and as shockless as is possible, for by far the great majority of these patients have but a fine thread holding

them to this existence and the mortality will be lessened by better technic.

The embryological aspect of the pericardium is rather interesting and makes the conception of its pathology comparatively simple. The pleural and peritoneal cavities are developed by a budding process from the body cavity. Later another budding process takes place from the pleural membrane or cavity, which develops into the pericardium. A bar arises and gradually inserts itself between the pleural and peritoneal sacs, eventually separating the two cavities. Hence, we may safely say that within certain limits the pathology of the pericardium will be that of the pleura and in all likelihood their diseases with some modifications will be the same. There is a divergency in this analogy in one respect, and while we shall speak of this later, it may be well to finish the comparison of the two membranes at this time. The subserous layers of the visceral pleura have only a few fibrous bands continuing into and becoming a part of the interlobular structures of the lung, while the visceral pericardium is closely and intimately related to the intramuscular septi. This proves of great pathological importance in pericarditis, particularly of the purulent variety.

Histologically the pericardium is a serous sac which encloses the heart and the proximal portions of the great vessels. It consists of two layers, one of which, the visceral layer, closely invests the heart and at its base becomes continuous with the parietal layer, within which it is invaginated. It is to be noted that the visceral layer is an exceedingly thin membrane and is throughout its extent so closely adherent to the outer surface of the heart that any attempt to detach it results in injury to the heart musculature. In fact, so close is this relation that many of the fibrous bands of the subserous coat are continued into and become integral with the intramuscular bands of the heart, similar to the close relation existing between the fascia lata and the intramuscular septi in the leg. There is a break in this close relationship and some fat may lie between the visceral layer and the heart over the ventricle and anterior surface. The parietal layer is much stronger than the visceral and forms a sac, the base of which rests upon and is attached to the diaphragm, while its apex surrounds the roots of the aorta and pulmonary artery. The two layers are in close proximity, save at the base where a small cavity exists containing liquor pericardii. At the sides and along a considerable portion of the sac, its anterior surface is in close proximity to the pleura. The upper part of the anterior surface where it covers the aorta is free from this contact; the lower anterior surface lies posterior to and is loosely attached to the sternum. Posteriorly, it is free to a considerable extent from the pleura, that portion covering the posterior surface of the left auricle resting upon the esophagus and the thoracic aorta. The point at which union takes place between the visceral and parietal layers corresponds to the upper margin of the second costal cartilage (39).

All authorities are agreed, that there is a great variation in the line of the reflection of the pleura and pericardium. Sick (6) reports that in adult findings in twenty-three cases, the pleura reflections at the level of the fifth cartilage lay either at or within the left border of the sternum in seventeen; at the level of the sixth, the pleural border had not gone beyond the sternal border in ten; at the level of the sternal articulation of the seventh in nine cases they were at the sternal border. Eleven children out of twelve, according to the same author, showed the pleural edge at or within the sternal border at the fifth costal cartilage; at the level of the sixth the pleura had not left the sternal border in eight children (6). Brooks, Luschka, Delorma and Mignon, and Dwight found the pleural margin either within or at the border of the sternum at the fifth costal cartilage in all their cases. The internal mammary artery throughout the first six interstices follows along the border at a distance of from one half to two cm.

As has been previously stated, a delayed diagnosis makes for a high death rate in the surgery of purulent pericarditis and to a less degree in the serous variety. The visceral pericardium being so thin, so intimately connected with the cardiac muscle, and the subserous coat sending so many fibres into the intramuscular septa, favors the advance of any septic process from the pericardial sac, by direct continuity of tissue, into the intramuscular septa and from here leading to an involvement of the musculature itself. Local abscesses are then the possibility and, if delayed, the probability, in all purulent pericarditis. Hence, you have to deal with a weakened heart muscle in every instance. This, in itself, forms no mean obstacle to successful surgery.

Of course, a diagnosis is essential and much has been said upon the subject of exploratory puncture of the pericardial sac. We believe this can be dismissed with a few words. It is a procedure not without some danger. To say that it is never advisable would argue for a diagnostic acumen which, unfortunately, has not been reached by most of us. To those so favored that a diagnosis is possible without recourse to this procedure, it may be unwarranted. To others, not so favored by an unerring diagnostic ability, it often becomes necessary. Owing to the fact that the heart occupies a downward and anterior position within the pericardial sac, the exploring needle is quite apt to injure the muscle and actually penetrate the left ventricle. While this might not cause much damage *per se,* it is at least undesirable to force pus and microorganisms directly into the blood stream.

Anesthetics in these cases must be administered with great caution. Local anesthesia theoretically is ideal, but in many hands does not work out. Ether and pus always make a lethal cocktail, the deadliness of which is proportionate to the degree of sepsis present and the amount of ether used. Ether, though, in experienced hands (and by this we mean experienced) seems essential in children. Nitrous oxide and oxygen have their place with adults and should generally precede ether at any rate. An adequate exposure of the pericardium is desirable in all operative procedures.

Many lines of attack have been suggested; some may be mentioned only to condemn them. Trephining of the sternum is unnecessary, does not furnish an adequate exposure and its margins are too inflexible. An incision over the xiphoid angle may involve

the diaphragm, may open the peritoneal cavity, and should the pus be loculated, of which there are cases on record, may result in not bringing the accumulation into a position to be tapped and drained. Resection of one or more of the costal cartilages then seems the only reasonable method of attack. It has all the good points and fewer of the bad ones than either of the others. True, there is danger of opening the pleura, but by careful dissection this can be successfully guarded against. Having decided, then, upon this method of approach, the operative procedure resolves itself into a few elementary steps.

1. Incision over the fifth or sixth costal cartilage about two and one half or three inches long, curved or straight at the discretion of the operator.
2. Strip back the periostum from the cartilage.
3. Reset the cartilage for adequate exposure and, if necessary,
4. Ligate the internal mammary artery above and below.
5. Retract the pleural overhang.
6. Incise and drain the exposed pericardium through the smallest possible niche, thus allowing a long time to elapse during the process of evacuation.
7. Investigate by palpation for any loculations or adhesions.
8. Drain.

The last of these steps is open to discussion. Whether or not the pericardium should be sutured to the wound edge or the skin for permanency in drainage will depend upon the circumstances governing each case. As a rule this procedure is not practical. Tube drainage is objectionable and is not advised. A rubber dam (rolled) changed daily, may be used, the result aimed at, of course, being adequacy of opening, maintenance of the opening and selfdraining facilities of the wound.

In the case here reported no drainage was used, the position of the patient being depended upon. By position is meant that the child was kept upon the left side, face down and feet elevated. As is seen by the records this proved to be quite satisfactory.

We cannot consider the case under discussion as being in any way typical of the condition under discussion. In the first place, this child had a complicated empyema of the pleura, which of itself is not extremely unusual. This we drained a few days prior to the discovery of the pericardial complication. Secondly, exploratory puncture failed to draw pus in the lower interspaces and it was not found until we tapped between the third and fourth cartilages. This fact made us feel rather uncertain as to the correctness of our diagnosis, as the loculated empyema of the pleura which we previously operated upon was in this location.

Because of the fact that we failed to recover pus in the lower punctures the incision (simply an enlargement of the previous thoracoplasty) was made over the third costal cartilage which was resected. After our dissection was completed, the edge of the pleura immediately came into view, the pericardium bulging very tensely, under great pressure. The pus in the sac was very slowly evacuated, and as said before, no drain was used.

We have never been able satisfactorily to explain our failure to get the pus in our lower punctures. We might ask ourselves, and properly too, what relation the preexisting (or was it preexisting?) pleurisy had to the pericarditis and thereby get into that old argument as to the possibility of a transmission of infection from the pleural cavity to the pericardium by direct continuity of tissue. Of course, this is undoubtedly possible, but does it happen? There seems much to say on both sides of the question and the difference of opinion held and fought over for the past decade still leaves us in doubt. We are of the opinion that direct infection rarely takes place and that most of the purulent infections of the pericardium are of metastatic origin. Yet here is a case in point which seems on its face rather to favor the other theory and to be one of the very unusual cases.

The authors' references will appear in their reprints.

Osgood-Schlatter Disease

JACOB GROSSMAN, M.D.
New York

Osgood-Schlatter disease is a disease localized in the tubercle of the tibia, characterized by swelling, tenderness and pain referred to the region of the tubercle of the tibia, with x ray findings revealing a wormeaten or eroded tubercle instead of a normal beakshaped tubercle, and usually follows overexertion or direct injury.

The ossification of the tibial apophysis occurs mostly between the twelfth and the fifteenth year. Between the first appearance of the bone nucleus and the completion of ossification, not more than three to four months are required. Only a thin cartilage zone remains between the tuberosity and the tibial diaphysis to about the eighteenth year. The apophysis sends a process over the anterior surface of the head of the tibia while from below an independent bone nucleus grows against it until, at the level of the epiphyseal disc, the fusion occurs. Schlatter concludes that there are extrinsic factors which contribute to this condition, for instance, that the ossifying apophysis is easily exposed to direct and indirect traumatism, especially at the point of junction between the upper or the lower apophysis.

Thompson reports a periostitis at the point of insertion of the ligamentum patellæ caused by a pull of the quadriceps.

Kienbock, upon the basis of his radiological findings, concludes, at least for some of the cases, that there exists an active destruction of the bone of the tuberosity together with an inflammatory

reactive swelling, in other words, an osteochondritis.

Ebbinghaus considers the condition as an epiphysitis dessicans traumatica. So it appears that the views on the etiology of this condition are by no means in harmony.

Bergemann pointed out that, aside from inflammatory changes, pathological changes of ossification analogous to those seen in late rickets are to be found.

Similarly Fromme, in a comprehensive clinical review, found that in a number of cases with late rickets the patients showed the signs of Osgood-Schlatter's disease, deducing from it that this disease occurs in the majority of patients afflicted with late rickets.

Hinrichs points out that if severe changes are seen in long bones in regard to ossification and growth, in a person afflicted with late rickets, such would also have to be expected to occur in the tibial apophysis where a comparatively thin bone plate rests upon a thick layer of cartilage. The pull of the quadriceps tendon may easily lift the process off its cartilage base and cause a kinking of the base of the apophysis. Severe signs of late rickets existed in all the cases which were studied. He concludes that Osgood-Schlatter's disease, in many cases at least, is merely a symptom of late rickets.

In our series of five cases there were no signs or symptoms of late rickets in any. There was a distinct history of injury in every one.

Osgood-Schlatter's disease occurs in a portion of the tibia which by virtue of its anatomical configuration and its exposed situation is especially open to direct or indirect traumatism. In all the cases in which the changes occur without traumatic influence, one should think of late rickets.

Usually there is a definite history of trauma, either direct or indirect, through striking the knee or through a sudden violent strain of the quadriceps muscle, such force causing separation of the fibres of the patellar tendon at its attachment to the upper diaphysis of the tibia and the tibial tubercle, which in adolescence is usually a beaklike projection from the upper epiphysis, overlapping the upper end of the diaphysis in its anterior portion and is separated from the diaphysis by cartilage.

The direct fibres of the patellar ligament are attached to this beaklike projection of the epiphysis, and, in addition, radiating tendon fibres are traced in a fanshaped distribution to either side attached to the tibial diaphysis. From this fanshaped distribution of the patellar tendon fibres it can be understood why the force applied does not produce a total inability of extension of the injured leg. In all cases there is some power of extension following such an injury, though this ability is greatly reduced and painful. This maintenance of partial ability to extend the leg following the injury is attributed to the remaining unruptured tendon fibres or to sprain or partial fracture of this tibial beak only.

The local swelling is attributed to the increase of bursal fluid set up by the trauma to the bursa lying between the ligament and the tubercle, plus infiltration resulting from the tearing of the ligament fibres and direct tissue damage. In comparing the injured knee with the normal knee one should remember that Osgood-Schlatter's disease may be bilateral; in such

FIG. 8. — Affected tubercle (right). Note the eroded appearance of the tubercle. Case V.

instances both x ray pictures being alike would naturally be called normal. In unilateral cases both knees should be x rayed so that the affected side could be compared with the normal one.

The chief symptoms of this condition are swelling, limping, local tenderness, inability to extend the affected leg fully, especially evident when walking up and down stairs.

In considering the differential diagnosis, an acute osteomyelitis or bone abscess might develop in this region, but a careful history and usually the presence of temperature, leucocytosis and x ray findings would rule this out.

Tuberculosis of the tubercle may also develop in this region, but the symptoms would not be so strictly localized and the progress of the disease, with bone destruction and x ray, would exclude this.

A bone cyst developing beneath the tubercle would give analogous symptoms, but a carefully studied radiogram would render the diagnosis unmistakable.

Pretibial bursitis would be very difficult to distinguish from disease of the tibial tubercle. If fluctuation could be determined or fluid obtained by aspiration, this would determine the case in favor of bursitis.

In the treatment of these patients the crisscross strapping with adhesive is usually sufficient. They do not suffer enough to justify keeping them in bed or even using a plaster cast or apparatus. They are, however, annoyed for weeks or months by the pain of complete flexion or extension, or when walking up stairs. They should be forbidden to indulge in rough sports.

The prognosis is uniformly good as to the end result, but the enlargement of the tibial tubercle may persist.

CASE REPORTS

Case I.—L. H., thirteeen years of age. Six months ago (prior to his visit to the office), the patient fell striking his right knee against the pavement. Shortly thereafter he noticed swelling of the upper part of the leg. He also complained of pain which he referred to the region of the tibial tubercle. The pain was aggravated whenever he walked up the stairs.

Examination disclosed a circumscribed swelling about the size of a silver quarter in the region of the tibial tubercle. Tenderness which was excruciating was also localized to the same area. Extreme flexion and extension were somewhat restricted and painful.

A tentative diagnosis of Osgood-Schlatter's disease was made and subsequent x ray pictures confirmed the diagnosis. (Figs. 1 and 2.)

Case II.—H. S., fifteen years of age. During the past two years the patient had bumped his right knee against the edge of a chair, on several occasions. The first few times the symptoms were so mild that he paid no further attention to the condition of his knee. After the last trauma had been sustained he noticed a swelling at the upper part of the right leg, which swelling was increasing. It was this increase in size of the swelling that urged him to seek advice. He complained of slight pain especially evident when he walked up stairs. He never noticed any redness in the affected region. Examination disclosed a circumscribed swelling slightly larger than a silver quarter localized to the tibial tubercle region of the right side. This area was somewhat tender. Extreme flexion and extension were restricted and painful. A diagnosis of Osgood-Schlatter's disease was made and subsequent x rays confirmed the diagnosis. (Figs. 3 and 4.)

Case III.—H. R., fourteen years of age. Ten days before his first visit, the patient, while walking came down forcibly on his right foot during which time he said he felt a sudden tightening of the muscle on the front of his right thigh. This was probably a sudden contraction of the quadriceps muscle. Shortly thereafter he experienced pain which he referred to the region of the tubercle of the right tibia. He also noticed that this area was swollen. Examination disclosed a circumscribed swelling about the size of a silver quarter localized in the region of the tibial tubercle. This swelling was very tender. Extreme flexion and extension of the knee were restricted and painful. There were no redness or constitutional symptoms present. A diagnosis of Osgood-Schlatter's disease was made and subsequent x rays confirmed the diagnosis. (Figs. 5 and 6.) In this case the etiological factor was the violent contraction of the quadriceps muscle.

Case IV.—E. R., thirteen years of age. Several weeks prior to the patient's visit, he fell striking his right knee against the floor. Shortly thereafter he experienced pain and noticed swelling in the region of the tubercle of the right tibia. Examination disclosed a circumscribed swelling in the region of the tibial tubercle, which swelling was about the size of a silver quarter. It was very tender. Constitutional symptoms and local redness were absent. A diagnosis of Osgood-Schlatter's disease was made and subsequent x ray confirmed the diagnosis (Fig. 7).

Case V.—J. R., twelve years of age. Six months prior to his visit, the patient fell and hurt his right knee. Shortly thereafter he experienced pain and slight disability. The disability and the pain gradually disappeared. The swelling, however, persisted and it was for this that he sought relief. Examination disclosed a circumscribed swelling in the region of the right tibial tubercle. Slight tenderness was also present in this area. There was no limitation of motion in the knee. Local redness and constitutional symptoms were also absent. A diagnosis of Osgood-Schlatter's disease was made and subsequent x ray picture confirmed the diagnosis (Fig. 8).

SUMMARY AND CONCLUSIONS

1. Osgood-Schlatter's disease is also known as starting of the epiphysis, acute epiphysitis, periostitis tuberositatis tibiæ, apophysitis tibiæ.

2. It occurs in children between the ages of ten to fifteen years. It is more common in boys than in girls.

3. In children under ten years of age there is no separate centre of ossification. The centre appears earlier in girls than in boys. It may appear earlier or be further developed over one tibia than the other. The separate centre for the tubercle begins to unite about the fifteenth year, usually earlier in girls than in boys and is generally firm by the eighteenth year.

4. Trauma plays an important rôle in the etiology. Symptoms or signs of late rickets were not present in any of the cases of this series.

5. Simple strapping is all that is required in treatment.

6. The prognosis is good as to end result, but the enlargement of the tibial tubercle may persist.

7. The condition is in many respects analogous to the similar condition in the hip often called Perthes' disease. Especially is this true of the radiographic appearance of the epiphysis in the two conditions. Both conditions occur in adolescence; the symptoms are moderate pain and tenderness and only partial loss of function. They are both self-limited diseases and usually recover without causing any serious or permanent damage to the parts affected. Kohler's disease or isolated disease of the tarsal scaphoid pursues a similar course.

The Bleeding Nipple

PIERRE TAPIE, M.D.

Bordeaux, France

The two following cases have induced me to make a few remarks on bleeding nipples.

Case I.—The patient, a female, aged thirty-seven years, entered the hospital in July, 1922, on account of bleeding from the left nipple, which began four months previously, although during the first three weeks the liquid was serous in character. There was no pain and no tumor could be detected. Examination merely revealed a bloody discharge from the nipple, staining the linen, while careful palpation failed to detect any distinct tumor. The nipple was supple and not retracted. The right breast presented nothing abnormal. There were large lymph nodes in the left axilla, but in the right only a small one, of no consequence.

As there was no distinct evidence of a growth in the breast, some hesitation was experienced as to the proper treatment, but on account of the bloody discharge and enlarged axillary lymph nodes, complete removal of the breast was done as a dendritic carcinoma was suspected. Examination of the specimen showed a small, flattened, lozengeshaped growth lying under the nipple. Histologically, the neoplasm was a metatypical intracanalicular carcinoma of the breast.

Case II.—The patient, a female, aged fifty-five years, entered the service of Professor Chavannaz, complaining of her left breast. She said she had always enjoyed excellent health, but about three years ago she was hit on the breast with the handle of a broom, which gave rise to much pain. This pain persisted until she was obliged to consult her physician, who found nothing but a small lymph node the size of a pea. He reassured the patient; the pain subsided, and she resumed her work. About eight months later a discharge of blood was noted, amounting to a few drops which soiled the linen. This lasted a couple of days and was followed by intense pain in the breast. She again consulted her physician, who prescribed an antiphlogistic ointment. The pain subsided but from that time on the little tumor increased in size, with occasional shooting pains in the breast.

In December, 1922, the pain became particularly severe and constant, so that the patient was admitted to hospital on January 20, 1923. The bleeding from the nipple had not recurred. Upon inspection, there was seen a slight tumefaction in the superoexternal quadrant of the left breast. By palpation a circumscribed hard mass could be felt, somewhat adherent to the overlying tissues, but movable over the underlying structures. The nipple was slightly retracted and the surrounding skin was a little puckered. There was a large lymph node in the left axilla. The right breast and axilla were normal. Operation was performed on January 25, 1923.

The specimen presented the characteristics of a carcinoma of the breast of the encephaloid type, with a rather rapid evolution. Histologically, epithelial masses were many and fully developed, being fed by a fragile fibrovascular stroma, especially the central parts of the neoplasm. Some cells are quite large, regular, and polygonal in shape, but others were small and invariably atypical. In other parts of the growth they retained a cylindrical shape with a commencing organization into glandular tubes. There were many islands of necrosis and one of the most important foci was the seat of a true hemorrhagic infiltration, the central part being absolutely liquefied. The walls were infiltrated with blood, especially the segmentary islands of hematic origin. A diagnosis of encephaloid carcinoma of the breast, with necrosis and hemorrhage in a focus of necrobiosis, was made.

Loss of blood from the nipple may be due to various affections, such as mastitis and aciniform carcinoma, but they are unquestionably exceptional. In some few cases loss of blood from the nipple results from benign intracanalicular papillomatous growths, but the most frequent cause of all is endocanalicular dendritic carcinoma.

Little need be said in respect of the predisposing causes of this symptom. It is most common between the age of forty to fifty years; one patient was thirty-seven, seven patients were between forty and fifty, while three others were over fifty. All the cases with which I am familiar occurred in women, most of them multiparous and having nursed their offspring. It has seemed to me that in some instances there was a relationship between menstruation and the loss of blood from the nipple. As reported cases show, this bleeding is nearly always the only symptom which attracts the attention of the patient. The discharge varies, sometimes being a serous fluid of a rusty red color, but usually it is frankly bloody. It may be fairly abundant or occur as a continued or intermittent discharge. There is rarely any pain in the affected breast, but pressure on the nipple may sometimes be painful. In a few cases the serous discharge

may precede the appearance of the blood for some little time, or possibly follow or alternate with it.

The presence of this symptom should at once lead to a careful inspection and palpation of the breast involved, in order to detect other symptoms which offer themselves. In the first place, no tumor or enlarged axillary lymph nodes can be detected, as in a case reported by Cabanne. The breast and axilla were normal, both by inspection and palpation, and it was only by pressing the nipple that some drops of blood could be made to flow out.

In my first cases there were a few enlarged lymph nodes in the axilla, palpation of the breast revealing nothing. In other instances a tumor will be found in the breast having all the characteristics of cancer, or at least offering distinctly suspicious characteristics of malignancy. Lastly, the growth may be encysted, as occurred in my second case. Usually the discharge of blood appears before the growth can be detected. In Professor Bégouin's case it was only after eight years that a small tumor was found in the breast, while in my second case the neoplasm was present several months before the blood from the nipple appeared, but this is most infrequent.

As the diagnosis, prognosis, and treatment are closely related to a bleeding nipple, it is proper to consider its clinical significance. Several conditions are met with in practice. There is a bleeding nipple and a growth in the breast. Occasionally the growth offers all the signs of a malignant process, viz., diffusion, adhesions, retracted nipple, and enlarged axillary lymph nodes, a typical picture of cancer of the breast. In these circumstances no hesitation is possible as regards prognosis and treatment. Operation must include the removal of the breast and contents of the axilla according to modern technic. In other cases the growth detected with a bleeding nipple is encapsulated, freely movable and not offering the characters of cancer, but rather those of a small cyst, frequently seated under the nipple. Now, although the physical characteristics of the tumor are not those of cancer, the bleeding nipple settles the diagnosis of intracanalicular dendritic carcinoma, and a radical operation is indicated.

There is a bleeding nipple without a tumor in the breast. This state of affairs may be embarrassing, but pathology shows that in the vast majority of these cases this symptom is due to dendritic carcinoma. In few instances is the loss of blood from the nipple dependent upon a mastitis or benign growths in a galactophorous duct. If the axillary lymph nodes on the affected side are different from those on the normal side, even when no growth in the breast is clinically appreciable, the coexistence of suspicious lymph nodes and a bleeding nipple should lead the practitioner to make a diagnosis of carcinoma.

When there is a bleeding nipple without tumor of the breast or enlarged axillary lymph nodes, the most prudent thing to do is to operate, because the chances are that the process is an intracanalicular carcinoma. This is especially true if the patient is over thirty-five and cannot be closely watched.

The Diagnosis of Acute Conditions of the Brain

With Special Study of the Spinal Fluid and Reference to the Child

J. VICTOR HABERMAN, M.D.,
New York

(*Concluded from page* 460)

HEMORRHAGIC ENCEPHALITIS.

When we examine other forms of encephalitis, namely, secondary encephalitis—hemorrhagic encephalitis,—as the condition is come upon in the infections, etc. (for full details, cf. 1), we find the spinal fluid either entirely negative or slightly blood tinged—occasionally strongly bloodtinged. Where the process has been severe, we know that considerable secondary bleeding (hemorrhage) may occur. There may be pressure or not. In other words, the spinal fluid in these cases determines nothing—though it may help our diagnosis per exclusion.

The onset of the condition may be described as follows:

During the course, or near the end, of one of the infections, there is a sudden rise of temperature (sometimes a chill), and with this, the appearance of general brain symptoms, i. e., headache, vomiting, a convulsion, followed by sopor or coma, with delirium after the coma subsides. For a day or two before, prodromata of malaise, headache, dizziness, or somnolence may have been noticed. In children, fever, vomiting and convulsions almost always occur; in adults, convulsions may be absent, as likewise temperature (the last frequently absent, it will be remembered, in poliomyelitis and poliencephalitis, i. e., Heine-Medin disease, sometimes absent in the epidemic form, and usually absent in the Wernicke type). The temperature comes down after a few days—though occasionally it may persist considerably longer. At times, yet rarely enough, there are cases in which sudden paralyses are noticed, with scarcely any previous indisposition. Holt even mentions a child going to bed as well as ever, awaking in the morning hemiplegic. There may be a single convulsion or a series (general, halfsided or Jacksonian), after which it is noticed that the child does not use its arm, has a facial paralysis (XIX) or is aphasic (XX); or this is first noticed after the coma, if present, lets up and consciousness returns. For the most part, pareses or paralyses are present by the second, third or fourth day, a matter of considerable importance in the differential diagnosis. During the early sopor or coma, a tremor may be seen in a limb, or choreiform movements, or jactitations (i. e., cortical irritation), usually in the limb later to be

found paralyzed. Or weakness in a limb is first noticed, which gradually becomes distinctly paretic, and then paralyzed (the paresis or paralysis being accompanied by hypertonus or spasticity). The involvement is, for the most part, *hemiplegic* (with involvement of the face; occasionally it is diplegic, rarely monoplegic).

Where there is a bloodtinged spinal fluid, one will always keep in mind the possibility of injury to vessels in making the puncture. However, the secondary encephalitides may show the same, especially influenzal encephalitis. An unusual hemorrhagic type of tuberculous meningitis likewise occurs with bloodtinged liquor (XXI), occasionally, also, as we have seen above, severe Heine-Medin cases. Finally, spontaneous and posttraumatic pachymeningitis with bloody liquor should be remembered, and a similar finding in cranial, cerebral or spinal injury after trauma.

Yet, though these various conditions may show up with a sanguineous tinge, or, indeed, much blood, in the punctate, this, on the other hand, may prove entirely clear. Other clinicopathological discrepancies also occur. Thus, in Bungart's scarlet cases (53), which on trephining, showed severe encephalitic softening, the pressure had been 300, fluid clear, albumin increased, no pleocytosis. In a case of Stadelmann's (54), the liquor had been bloody and under high pressure, the same being found in three repeated punctures. The diagnosis was either meningeal or ventricular hemorrhage. Necropsy, however, revealed not a hemorrhage, but an encephalitic softening. In a group of anthrax cases reported by House (55), several showed brain complications. In two, anthrax had not been suspected until after death. The spinal fluid was bloody. In these cases, there was a meningoencephalitis, with edematous destruction of the tissue—and the finding of the anthrax bacillus in the lesion. In Lambert's case of poisoning by hydrocyanic gas (56), the spinal fluid had been under normal pressure, gave a cell count of 207, 45% of which were polymorphonuclear. This (and the symptoms) suggested purulent meningitis. Necropsy revealed only an encephalitis, with evidence of small hemorrhages in the white areas, and neuronophagia changes.—In rupture of a cerebral aneurysm (or occasionally an artery), the liquor is nearly always bloody. This usually occurs only after an injury or strain.

In this entire series of cases, we can see how diagnostically misleading the spinal fluid may prove—how little differentiating help it may afford us. There are still several other conditions come upon—often intimating an encephalitis where this does not exist, and which should be remembered, for here, too, the spinal fluid gives no diagnostic aid. Thus, in many cases of botulism, the liquor shows nothing, and necropsy reveals nothing abnormal in the brain. It has been suggested that in some of these cases, the toxemia has been so intense and fulminating that death occurs before brain changes have had time to develop. The negative brain findings—even in animal experimentation—have prompted the surmise that the lesion produced by botulinus toxin is on the peripheral nerve terminals (57, 58). Insulation is another such condition. There may be excess of cerebral fluid here, though it seems likely that inflammation (or hemorrhages?) may also occur (XXII). In pertussis, one likewise sees pictures which at times intimate hemorrhage, or, encephalitis, yet in which nothing but serous meningitis is found. The brain itself may show a serous saturation. Thus, a case of Finkelstein's (60) is of considerable interest. This belongs to the chapter of meningitis serosa—but is given here because of its great resemblance to cerebral hemorrhage as one sees it in pertussis, or to encephalitis:

Case V.—E. F., one year old. Following an intense paroxysm on January 26th, severe convulsions. High temperature, coughing, vomiting, bronchitis; February 8th, irritability, somnolence, transient strabismus, jerking in the extremities, together with increased bronchitis. On the tenth, the temperature rises to 40.5°-41° as convulsions set in, repeated many times, also in following days. Between these attacks, sopor of changing intensity. Rightsided abducens paresis, strabismus, unequal pupils, stiffness of the neck, automatic movements, spasms and paresis of extremities, considerably severer on the left side. March 5th, severe convulsion, with exitus. Necropsy: mild ependymitis of the lateral and fourth ventricles and slight hydrocephalus internus. Bronchitis. Brain, itself, negative.

In contrast to the condition of serous saturation, one must bear in mind the cases of brain swelling, a swelling of the brain parenchyma itself (Reichardt). In these cases, the brain becomes larger than the skull capacity. Very little liquor, indeed, may be present. The brain here is dry.

Apelt (61) found the condition by no means infrequent (in infectious diseases, uremia, typhoid sepsis, pseudotumor, etc.). It might come on with great rapidity. In a case of Apelt's, the patient, while eating, suddenly fell to one side and died. The skull capacity was found seven tenths per cent. smaller instead of ten per cent. larger (as is usual).

In connection with brain edema and brain swelling, we must also think of uremia and eclampsia. The symptoms in both these conditions may be identical with those found in hemorrhagic encephalitis. In fact, brain edema is often the underlying pathology (XXIII). There may be convulsions, a hemiplegia, hemianopsia, etc., and necropsy discovers nothing. In scarlet fever with kidney involvement, the onset of cerebral symptoms may portend a meningitis serosa, an encephalitis, a uremia. If there happens to be an otitis present, there may also be a serous meningitis from neighborhood irritation, an otitic associated encephalitis (Oppenheim), a brain abscess, a sinus thrombosis! Lumbar puncture brings little or no diagnostic aid. A high urea content in the blood may point to uremia. (Here uranalysis, blood chemistry and blood pressure may aid.)

In adults, a socalled pseudouremic condition, with similar brain symptoms, may be occasioned by focal softening through the closing of cerebral arteries in cases of arteriosclerosis. Such a patient frequently has a kidney involvement, in which case the exact diagnosis may become puzzling.

MENINGITIS SEROSA.

In close association with encephalitis, one must consider meningitis serosa, which often enough accompanies the former, and constantly proves a prob-

lem. It is a serous inflammatory process—reaction—in the leptomeninx (XXIV), either external (convexity and base, or in circumscribed irregular areas) or internal (intraventricular), or both, and may be called forth by the toxins of the infectious diseases, the ingested or endotoxins of gastroenteritis, the exanthemata, syphilis, autointoxication, acidosis, cerebral trichinosis, cysticercus, brain trauma (i.e., violence to skull) and by the way of socalled neighborhood irritation (Oppenheim), as in otitis (in which a meningitis sympathetica may also occur), or abscess, or as a "foreign body irritation," i. e., in pachymeningeal hematoma. Quincke even thought that in intracranial hemorrhage, the blood itself might possibly act as a foreign body, and irritate the meninges to secretion. As just stated, it not infrequently accompanies encephalitis, primary and secondary. Not long ago, the New York Health Department pointed out the possible appearance of decided meningismus in severe sore throat (65), and Göppert (66) called attention to its frequent existence in mild febrile affections of the upper respiratory tract (nose, nasopharynx, etc.). This serous oversecretion is accompanied by a migration of small lymphocytes—a few or many (XXV). In such cases, the spinal fluid shows:

Clear fluid; at times, slightly turbid (if many cells are contained).
Sometimes pressure (a little to very considerable), sometimes none.
Lymphocytes may be sparse or numerous.
Ordinarily no bacteria (sometimes, however, a few bacteria are come upon [pneumococcus, streptococcus, etc.] (XXVI).
Phase I.—opalescent—weak+; 20% fraction, negative (Kalfka).
Albumin in excess of the normal.
Hemolysis, negative.
Sugar reduction often.

Thus, one can see how the liquor findings here may be similar, or even identical, with that of poliomyelitis, epidemic encephalitis, tuberculous meningitis (where the t. b. c. is not found), or even syphilis (cf. Gennerich on metalues). Diagnostically, a difficulty also arises, inasmuch as meningitis serosa not only often accompanies encephalitis, but frequently occurs in the very diseases (the infections) in which we also find, or may expect, an encephalitis. The studies of Herrick and Dannenberg (68) showed that a serous meningitis may be present and severe, with little or no clinical evidence, and, again, be mild in the face of decided clinical manifestations. It may be severe in cases where one would least expect it (tonsillitis, mumps). The liquor may at times be under considerable pressure; the lymphocytes (rarely polymorphonuclear) be numerous—far more so than hitherto suspected, well above a hundred, in one case up to 200 (XXVII). However, cell counts above a hundred will usually make us think of Heine-Medin disease or syphilis. (It must not be thought, though, that the liquor of these two diseases always has a high cell content; occasionally this is quite low).

The symptoms of serous meningitis are chiefly those of pressure—headache, vomiting, retraction of neck—sometimes evidencing great fluctuations (this helping in the diagnosis. (Cf. Finkelstein's case, above). Often pressure develops slowly; yet it may come abruptly (apoplexia serosa). In the intraventricular type, the rapid effusion (acute hydrocephalus) may suddenly prove serious. The consequent convulsions which set in may be prolonged and sinister (XXVIII). The symptoms of brain pressure are usually mingled with those of the primary disease. In the gastrointestinal cases, this disorder may be intense, and the temperature high. In very young children, in fact, intestinal disorder and temperature are frequent. In infants, laryngospasm may be associated. Indeed, spasmophilia (and rickets), with its over reactionability, must always be borne in mind when appraising the brain symptom complex in children—i. e., the infection need not be over virulent, but the reaction of the patient's nervous system may be abnormally severe. Attacks may even end fatally in such a (spasmophilic) child, and nothing of encephalitis or meningitis be found. Where either of the latter, however, does occur, the effects are decidedly stormy.

In the early days, the first three or four, the differentiation from encephalitis can scarcely be made, the liquor in encephalitis showing nothing characteristic. In the encephalitis cases in which coma and convulsions continue, the differential diagnosis remains impossible. In other cases, however, *paralyses (hemiplegia, facial) will almost always be present by the third or fourth day in encephalitis, while in serous meningitis, hemiplegia and paralyses of cranial nerves rarely occur* (XXIX).

In infants, the head bones give, and, so, pressure symptoms may be avoided. In such cases, there even may be no symptoms (due to the meningitis) at all. In older children, the pressure may remain slight or become intense. Sometimes there is a fluctuation, with spells of severer pressure, which again let up. Such variability—i. e., fluctuation—will speak for meningitis serosa as against hemorrhage (XXX).

The blood shows nothing. A lymphocytosis may be present, due to the underlying condition. A high leucocyte count may point to a suppurative condition not previously suspected.

PURULENT MENINGITIS

Of the nonserous meningitides, the *epidemic form* is clinically characterized by violent headaches and pain in the nape—coming on rather suddenly, together with vomiting and vertigo. Usually there is nuchal rigidity, usually opisthotonus. Hypersusceptibility of spine, skin (tache) and muscles will be found, and, for the most part, scaphoid abdomen, Kernig, Brudzinski, sometimes Babinski, frequently labial herpes, and irregular, irreactive pupils. (Recently a new sign of meningitis has been pointed out: the auricularis sign, i. e., a hyperesthesia of the posterior wall of the external auditory meatus—without hyperesthesia of the anterior wall (70). Possibly other sources of irritation, beside the meninges, may give the sign (71). There may be an exanthema (petechial). These children have many convulsions—and cry much. On the other hand, retraction of the neck is often absent, especially in infants. In such, the disease may at times show no more than high temperature and rapid pulse. Should there be no retraction to suggest meningitis, there may be a bulging fontanelle. Again, in some infants, this is present, in some it is not. Thus, lumbar puncture must give the diagnosis, i. e., a purulent fluid, con-

aining polynuclear leucocytes, and the diplococcus ntracellularis.

There are cases in which the pus, because of a asting up of the meninges, does not get into the pinal fluid—which remains clear (cf. footnote No. XXIV), and may be under pressure. Through ulture the diplococcus may, however, be obtained rom this clear fluid (Thiemich (72). These cases, owever, cannot be frequent.

One may, in general, rubric the purulent menin-itides as follows:

Appearance: turbid, like pus, often xanthochromous.
May, or need not, be pressure.
Cell count strongly positive—usually uncountable, mostly olymorphonuclear leucocytes.
Phase I, three plus; 28 per cent. fraction, plus (Kafka).
Albumin increased.
Sugar decreased.
Hemolysin reaction, three plus, (Kafka).
Mastix and colloidal gold: meningitis curve.

Two epidemics of myositic pseudocerebrospinal neningitis have been noted (Lenhartz, Curschmann (73)), the disease being characterized by myositis of he neck musculature, with participation of the rticulations of the cervical vertebræ, clearing up promptly on aspirine.

Tuberculous meningitis is easily differentiated from the epidemic, inasmuch as it does not begin acutely: it has a characteristic prodromal stage (decided change of mood, apathy, severe anorexia, loss of weight, disturbed sleep, vomiting, etc.). Yet, occasionally there are cases in which this period is missed (Nonne, Zappert)—while, in young infants, little change need be noted.

The disease begins with headache, temperature, apathy and vomiting. The pulse, in spite of the temperature, is slow and irregular. There is nuchal rigidity and hyperesthesia. Kernig is often present, abdomen scaphoid, pupils irregular, slow in reaction, mostly contracted. Choked discs may be seen. After two weeks, the paralytic stage comes on—strabismus, ptosis, pareses of face and basal cranial nerves and extremities, etc.

The tubercle bacilli in the liquor give the diagnosis —only one does not find them so easily. There are very few in number at the beginning of the disease—must be looked for—and are found only after diligent search, often only on the second or third puncture (XXXI). Rarely, they are not discovered at all, even with animal inoculation. The fluid is usually clear or very slightly turbid, or slightly yellow (or sanguinous in the hemorrhagic type, cf. above), under pressure (high at the beginning of the disease), containing small mononuclear leucocytes. A fibre net is set off, but this no longer is found pathognomonic, as it is occasionally found in Heine-Medin disease, epidemic encephalitis and in syphilis. (Nonne [l. c. Pette] found it in a case of acute syphilitic meningitis; Gennerich in luetic meningoencephalitis; Quincke in both syphilitic meningitis and serous meningitis.)

Tuberculosis in the family or the patient, apices (x ray of lungs) bones, joint (coxitis) glands, tubercle in the choroid) will make us strongly suspect the meningitis to be tuberculous. It may also be remembered that the syphilitic infant, or child, is very prone to tuberculosis. (In Hochsinger's series, 80% of the deaths occurring in syphilitic infants after the second year, were due to tuberculosis (75).) One may suspect something also after measles and pertussis. This is preponderantly a disease of infancy and childhood—only occasionally seen in an adult.

Our liquor schema would read as follows:

Clear usually; (web after twenty-four hours; this may, however, be absent in the first or second puncture). Occasionally slightly turbid, or slightly yellow, or, rarely, hemorrhagic.
Pressure usually increased; early, may be very considerable.
Cell count mostly small lymphocytes, a few or many: sometimes leucocytes (XXXII).
Tubercle bacilli in liquor (when found).
Phase I.—weak positive.
Slight increase of albumin.
Pandy: always positive. (*Without positive Pandy, strong doubt as to condition being tuberculous.*)
Sugar *decreased.*
Mastix and colloidal gold: meningitis curve.
Blood gives a positive (rapid) corpuscles sedimentation.
Blood gives a positive Mátéfy (see below).

In the remaining purulent bacterial meningitides, the liquor will reveal, besides more or less pus, the special organism of the disease (pneumococcus, diplobacillus pneumoniæ, Friedlander, Pfeiffer, staphylococcus and streptococcus, colon bacillus, occasionally the lactic aerogenes, rarely the pyocyaneus, bacillus dysenteriæ, very rarely the Gaertner (77), typhoid, the paratyphus-B, the gonococcus, yeast infection [Türk, cited by Lenhartz (78)], the streptothrix (79), micrococcus tetragenes, and proteus). The disease in these cases being usually secondary, the primary condition may serve as index of the possible or certain source (wound of skull or scalp, otitis, sinusitis, ethmoid, sphenoid or nasal ulceration, abscess of tonsil, occasionally retropharyngeal abscess (XXXIII), or foci of suppuration elsewhere (pyemia, typhoid (XXXIV), pneumonia, bronchiectasis, abscess of lung, pyelitis, foci of bone suppuration, pyodermia, erysipelas, etc.]). A meningitis sympathetica has been described (l. c. 76), a condition due to neighborhood irritation, especially seen where otitic abscess is the source of irritation, clinically giving a picture of meningitis; the spinal fluid showing pressure and containing polymorphonuclear leucocytes, increased albumin, but no bacteria —i. e., asceptic purulent meningitis. The fluid is turbid from the content of pus cells. Occasionally, however, here, as in other purulent liquors, the appearance may be clear. The resemblance to meningitis serosa due to neighborhood irritation is evident —save that in the latter, no polymorphonuclear leucocytes are usually found in the spinal fluid. In the cases reported, the prognosis was serious.

Yet the diagnosis of meningitis sympathetica should be made with great reserve. Just as in tuberculous meningitis, bacteria may here be found on the second or third puncture—or even later search. Animal inoculation should also be made. (Nor ought a few bacteria to influence the diagnosis, if such a purulent reaction can be called forth by neighborhood irritation. It may be remembered that a few bacteria are likewise often found in serous meningitis [l. c. above].) But it appears that even in serous meningitis, numerous polymorphonuclears may at times be found, judging from the case reported by Kilduffe (82). Interesting is the fact that

polynuclears may be present in abundance in the liquor of a case (cf. Lambert's) in which an intense encephalitis obtains, and no meningitis at all. There are also cases of poliomyelitis, we should remember, in which polynuclear leucocytes are found in the liquor— and no bacteria! Ayer (83) found them frequently, and in considerable numbers, in the first twenty-four hours. In the cerebral form of the disease (Heine-Medin encephalitis), Koplik (84) saw a case which strongly resembled tuberculous meningitis. Even the von Pirquet showed a 2 mm. positive reaction. Spinal fluid contained no bacteria, and on the second puncture, seventy-two per cent. lymphocytes, with twenty-eight per cent. polynuclears, albumin 1 mm., slight sugar reduction. Finally, in the report of the Department of Health of New York City on the poliomyelitis epidemic of 1916 (l. c.), polynuclears predominated (over fifty per cent.) in thirty-nine out of fifteen hundred spinal fluids examined. However, a polynuclear liquor free of bacteria, especially in the absence of etiological or clinical clues, will make us think of a sympathetic meningitis, and search for a cause of meningeal irritation, especially abscess, or ethmoid or sphenoid disease (85). (Aseptic purulent meningitis has also been described in ptomaine poisoning, diphtheria, parotitis, uremia, eclampsia, syphilis, and after spinal injection of serum.)

Difficulties in differential diagnosis between Heine-Medin disease and epidemic, and especially tuberculous, meningitis arise. The second may at times look very much like the first (cf. Koplik's series (84)) (XXXV), though this is extremely unusual. With the tuberculous form, if the organism is not found, the temporary quandary may prove embarrassing. If paralysis appears at once, especially flaccid signs in the limbs, Heine-Medin may be diagnosed. Here paralyses almost always come early; in tuberculous meningitis, they usually come late. The decreased liquor sugar of the latter disease may give a slight clue, as well as the variance of the mastix curve. The tuberculin reaction does not seem conclusive (cf. Koplik's Heine-Medin case in which it was present). A choked disc will speak for tuberculosis—but it only manifests itself late. The most constantly positive and earliest sign noted by Rominger (86), out of Noeggerath's clinic, was the Pandy reaction. In the cases giving a negative Pandy (grippe with serous meningitis, spasmophilia, dyspepsia, encephalitis acuta, double pneumonia with brain edema following pertussis in a tuberculous family!), no tuberculous meningitis developed. This test seems very sensitive and apparently reliable. As to the action of the Pandy test in Heine-Medin disease, I have no data. Finally, the corpuscles sinking time (or sedimentation test), brought out by Fahraeus (87), may help decidedly in the diagnosis of tuberculosis. The sedimentation rapidity for the normal, in a 1 cm. tube, was found to be 3 mm. per hour for men, and 5 mm. for women (88). More rapid sedimentation spoke for tuberculosis, while normal values spoke against it. In doubtful readings, 0.03 to 0.1 of old tuberculine was injected into the patient—and it was found that, if normal, the sedimentation time remained the same, but if tuberculosis obtained, this procedure hastened the sedimentation. In children, it appears merely a Pirquet or Moro need be made for the test. Dehoff (89), who suggested this last measure, speaks very highly of it. Freud and Henschke (90), on the other hand, did not think a normal sedimentation time excluded active tuberculosis with certainty. They give the sinking time as six and one half hours for men, and four and one half hours for women. For the technic, see this sulphate last article.

A much simplified method of the above appears to be given in Mátéfy's globulin test of the blood serum (91). (One half per cent. solution of aluminium sulphate. [freshly prepared] added to 1 to 0.2 c. c. of serum. Shake. To stand at room temperature for one and one half hours.) Normal sera show a more or less strong turbidity, but no flocking. In the abnormal sera, there is a thick sediment of globulin. The greater the intensity of the disease, the more rapid the flocking process (92). The test is not pathognomonic of tuberculosis; it also occurs in syphilis, carcinoma, nephritis. This test, like the above, is distinctly valuable in prognosis and gauging the efficacy of various treatments.

That tuberculous meningitis may at times resemble epidemic encephalitis has also been pointed out (93). (Below, we also mention the resemblance of acute syphilitic meningitis to the tuberculous form.)

Differentiation between typhoid and tuberculous meningitis may come up, especially early, before the Widal is positive. The Diazo test may help to point to typhoid; the Pandy, if present—and present early enough—to tuberculous meningitis.

Uremia may look like tuberculous meningitis (urine findings). But one will also think of a tuberculous nephritis, with terminal meningitis. In a case seen by Zappert (94), a picture resembling tuberculous meningitis was present—with a dark or reddish urine. This proved to be a case of hemorrhagic nephritis—with no meningitis at all, though meningitislike symptoms had been given. In another case on record (95) with meningitic symptoms, the lumbar puncture did not evidence tubercle bacilli, but a high percentage of albumin and urea. Urine and eyes were negative. Two weeks later, convulsions came on, with renewed symptoms, the liquor now showing urea 3.45, and chloride 7.4 per thousand. Exitus. Necropsy showed a tuberculous pyelonephritis, and no meningitis.

(*To be concluded*)

Röntgenotherapy of Peritoneal and Genital Tuberculosis.—Wolfgang Uter (*Zentralblatt für Gynakologie,* July 5, 1924) believes that röntgenotherapy is the best form of local and general treatment for peritoneal and genital tuberculosis, as it has no mortality, produces no fistulæ and maintains the genital function. The proper dose is at first one eighth to one twelfth and later one twenty-fourth to one forty-eighth of the skin unit dose, including four to six exposures from the umbilicus to the symphysis pubis and without protective covering. Exploratory laparotomy may be necessary on account of the difficulties of diagnosis, but only caseous salpingitides should be operated upon. With lesser and moderate adnexal tumors, as well with peritoneal and more general involvement, the abdomen is closed and subsequently only irradiation is indicated.

Therapeutic Possibilities of Small Doses of X Rays

CHARLES F. STOKES, M.D., D.Sc., LL.D., F.A.C.S.

New York

With the growing interest in biophysics in medicine, even among conservative physicians, it is perhaps timely to speculate in the fields of physiology and pathology in terms of the electron theory. Indeed, to understand the behavior of living cells in health and disease the physical factors must be considered for they are primary and basic. The literature in this field has grown enormously of late and is enlightening. It is the belief of many that our greatest advances in diagnosis and in therapeutic measures are coming out of the physics laboratories. The part played by colloids in the physicochemistry of cell structure and function is most interesting and important. In this connection I quote R. S. Lillie (1924), who says, "It is most important to note that in the inorganic systems (battery or electrolytic cell) in which the passage of a current induces chemical change the reaction occurs only on the surface of contact between the electrolyte solution and the electrode, not in the interior of the metallic or of the electrolytic phase. Electrochemical reactions are surface reactions. This general fact is to be correlated with the general physiological observation that the critical or initiatory changes in stimulation originate at the surface of the irritable element, i.e., at the boundary between the cell or cell structure and the surrounding medium. Surface reactions are those concerned in the initiation of stimulation and apparently also in its spread. A brief résumé of the chief facts indicating this relationship of surface changes to stimulation may now be added.

"An especially significant fact is the sensitivity of many cells to slight mechanical contact; this is seen in a great variety of organisms, and indicates that the physical effect releasing the propagated disturbance need affect directly only the cell surface. Blood corpuscles and other cells frequently break down on the contact of capillary needles; contact sensitivity of all kinds illustrates the same condition. Chemical stimulation and chemical alteration of irritability (anesthesia, sensitization) appear also to be surface effects without evidence of penetration into the cell interior; examples are the stimulation and sensitization of muscle and nerve by isotonic salt solutions (calcium precipitants, etc.), anesthetization by magnesium salts and isotonic sugar solution; increase of oxygen consumption in sea urchin eggs by nonpenetrating alkalies (sodium and potassium hydroxide). In the case of electrical stimulation the quantitative determinations of Nernst, Lapicque, Lucas and others, showing the parallelism between the stimulating action of the current and its polarizing action, also indicate that stimulation originates at the polarizable surfaces of the cell, i. e., the semipermeable boundary layers of membranes. That this is the case is also indicated by many characteristic structural conditions in the nervous system of higher animals and in other regions where stimuli are transmitted from one cell or irritable element to another. Nerve end plates spread over the surface of the muscle cell, effecting intimate contact but not penetrating; nerve cells in the central nervous system are related to one another by means of end feet, interlacing terminals, or similar structures which establish contact without penetration or protoplasmic fusion. From these various facts we must conclude that in irritable cells the plasma membrane is not merely a protective layer, but plays the part of a sensitive intermediary between the external world and the internal protoplasm.

"The indications are that any slight local physical change at the cell surface, causing stimulation of the cell, does so by altering the electrical conditions at that area, thus initiating an electrically transmitted disturbance. This view implies that all forms of stimulation are electrical; i.e., the primary stimulating agent produces its effect by changing locally the electrical potential at the cell surface."

Burns and Alexander point out the enormity of the increase in effective surface that takes place when a cube whose length of edge is one cm., is divided into cubes or particles of colloidal size (total surface of one cubic cm.=0.93 sq. in.; same bulk in colloidal particles, total surface 1 $\mu\mu$=1.48 acres).

The living organism may be looked upon as a stupendous mesh work of semipermeable membranes, enclosing protoplasm in cellular dimensions, integrated into physiological gradients and systems of organic structure to meet the needs of the individual or the species in his battle with his environment.

Chemically protoplasm may be considered a watery solution of colloids and crystalloids. It has been demonstrated that colloids, as a rule, carry an electric charge, some positive, some negative, the sign depending on the nature of the colloid and on the nature of the medium in which it is. The particles in colloidal solution are supposed to be vibrating with the same frequency as light of a certain wave length and will receive energy from that light which will tend to increase their amplitude of vibration.

Only that light, or radiation, which is absorbed is chemically active. Since absorption is apparently due to resonance in electron oscillations with the incident radiation frequencies, we can or should be able, within limits, to vary our wave lengths and frequencies, by rearranging our factors to meet any level in the body in x ray doses that may be indicated.

A word about the physics of the cell. The nucleus is electropositive and acid; the cytoplasm electronegative and alkaline, and these are in dynamic equilibrium separated by a semipermeable membrane. When static equilibrium is brought about the cell is dead. When the cytoplasm has been depleted of electrons the affinity for oxygen is lessened, a condition of suboxidation ensues, the cell approaches a positive charge and an acidosis follows with the probable formation of lactic acid and hydrations. All normal syntheses of the cell are condensations with dehydration. Pathological tissue is positive in charge except perhaps in conditions of pathological inhibition.

Professor Albert P. Mathews (*General Cytology*, 1924) is so closely in line with the substance of some of my earlier papers that I am quoting him freely.

"How then can energy, i.e., electric current times magnetic flux, be transferred from one molecule to another? It may be transferred in a variety of ways.

"1. It may be transferred by radiation in a series of pulses. Each radiant pulse contains a certain amount of magnetic flux and electric quantity. It contains 6.55×10^{-27} ergs seconds. If some of this magnetic flux and electric quantity is absorbed, this quantity per second is called absorbed energy. Thus the atoms of matter in the sun radiate from themselves these pulses as the solar atoms die. Some of these pulses being absorbed raise the store of energy in the molecules about us. In particular they raise the energy of the oxygen of carbon dioxide to form the energy-rich atoms of oxygen in oxygen molecules. These latter are the springs from which later we obtain all our energy. The electric and magnetic flux of the etherial pulses sent from the sun are caught by the molecules of carbon dioxide, not directly but indirectly through the agency of chlorophyll and stored in the unstable reservoirs of the oxygen molecule. Actually the potential energy of the oxygen molecule is raised by the passing of certain electrons in the molecule to a position farther removed from the central positive nucleus of the atom, or to a position of greater instability. According to Bohr one or more of the electrons move outward so that they are in orbits of larger radii, having a greater energy. Formaldehyde is also coincidently formed, and the carbon atom in it probably has somewhat more energy than the carbon in carbon dioxide. The formaldehyde thus formed absorbs light energy in its turn (wave length 250 $\mu\mu$), and is transformed into a more reactive kind which condenses at once to carbohydrates, and in the presence of nitrates makes formhydroxamic acid, amino acids, and other compounds.

"The chlorophyll in the foregoing instance acts the part of a catalytic agent, that is, it acts the part of a conductor of energy from the light pulse to the molecule of carbonic acid. All catalytic agents act probably as conductors of energy. Chlorophyll is a photocatalytic agent, that is, it conducts the energy of light to another subsance, carbonic acid.

"2. But the energy may be transferred not by that form of electric quantity times magnetic flux known as light, as a series of pulses in the ether; it may be transferred in that form known as an electron. We have not yet discovered a method of transforming these two kinds of energy seconds, namely, an ether pulse and an electron, one into the other. Perhaps it cannot be done, although they are essentially the same in nature. But we know that molecules or atoms may part with their energy in either one of these two ways, either by radiating another pulse, that is, radiant, reversible energy time, or by discharging an electron, a quantity of irreversible energy time. For this electron, or permanent ether pulse, to be shot out from the atom a considerable quantity of energy time must usually be absorbed. The electron usually leaves at a rather high, indeed at times a very high, velocity. The velocity with which the electron is radiated depends upon the amount of energy absorbed, that is, it depends upon the energy content of the ether pulse which is absorbed. For since, in all ether pulses the total product of energy time is a constant, some pulses will have a great energy content and little time; others will have a small energy content and a large amount of time; that is, in the one case the energy content is high but the period of duration is short; whereas in the other the energy content is low but the period is long. The velocity of expulsion of an electron is then dependent upon the energy content of the pulse which expels it. So the very short waves of great energy content of the period corresponding to x rays cause the expulsion of electrons with a very high velocity; while the feeble rays of the red spectrum expel them at a very low velocity. All of this is of importance in understanding color vision. It is well known that the shorter waves, with the greater energy content, those in the violet and ultraviolet, produce very intense chemical changes. Thus, for example, the energy of the silver atom is so greatly reduced by exposure to ultraviolet light that it is no longer toxic or poisonous. It becomes the inert metallic silver. By the action of light an electron is transferred from another atom to the silver atom leading to a far more stable arrangement of the electrons of the silver. The radiations of electrons under the influence of light are beta radiations. They come from certain atoms under certain conditions. Negative electrons may be given off from almost every form of matter. And their absorption may either raise or indirectly lower the store of energy in that atom or molecule which has absorbed.

"The action of x rays is generally attributed to their powers of producing a radiation of electrons at a high velocity from certain atoms of the tissues through which the x ray passes. An x ray thus has

a double effect, namely, a direct effect upon the atom which has lost the electron and also an indirect effect due to the electrons which have been shot out of one atom changing the state of another which picks it up. As the electron is not radiated in the direct line of the x ray, a scattering of electrons is thus produced which increases the radius of the area affected by the x ray. Inasmuch as the velocity of the expelled rays depends upon the energy content of the x rays absorbed, and this is higher the shorter the wavelength, or, as is generally stated, the harder the ray, so the shorter, harder more penetrating x rays produce an electronic discharge at a higher velocity than do the softer. The secondary radiations thus produced as they have a higher velocity will radiate farther before absorption. So the harder the ray, the greater will be the cross sectional area as well as the death of the tissue affected by the ray.

"Inasmuch as the more reactive tissues have their molecules in the least stable form, these tissues will be the easiest to affect by x rays. Thus, dividing cells in which the metabolism is very intense, as Lyon showed, are very easily destroyed and cancer tissue also. But there will be a boundary area in any x ray irradiation in which the anakinetomeric molecules will be increased. If this boundary is cancerous the ray here may increase cancerous growth.

"3. But the third, more common, and easier way to transfer energy is by means of conductors of electricity. To set up a pulse in the ether requires either a great deal of energy action for a short time, or a small amount acting for a long time. The value of h, the minimum amount of energy times time which must be accumulated before radiation can occur, is 6.55×10^{-27} ergs seconds. Similarly to discharge electrons by radiation requires a considerable increase in energy, in many cases at least. Between substances, however, at a slight difference of level, or potential, of energy an exchange may take place if only they are connected by what is called a conductor. If two charged plates of a condenser at a different potential are connected by a metal, the electric potential is equalized. The metal acts the part of a path interposing little resistance to the flow of electrons along it. For such an exchange to occur, energy must be at a difference of potential.

"Now imagine the condenser plates reduced to the size of two molecules each of which contains free energy but at a different potential. If only we could connect these two molecules by a conductor, energy would pass from one to the other. Such conductors exist. We call them catalytic substances. Or the energy may pass directly, the substances uniting in a conduction union with each other. In either case, for such an interchange of energy between molecules to occur the union must be of a conducting nature. The two molecules must make such a union as to permit electrical charges to flow from one substance where they are at a higher potential to another molecule or atom where they are at a lower. In all ordinary exchanges of energy in chemical reactions of every kind, it is necessary hence for the two molecules or atoms so to unite as to make good conductors of electricity. If the molecules cannot themselves so unite it is necessary that each unite with a third, which thus is interposed between them as a conducting system. In all such cases as these the potential energy of the system is due to an electron placed in a certain position. By transferring that electron to another system the one system loses potential energy, the other gains it. It is because electrons have to be transferred in this method of carrying energy that the transferrer must be a conductor of electricity."

If we indulge further in speculation which I believe we may with propriety, and look upon some, at least, of the pathogenic organisms, in their behavior, as foreign cell nuclei devoid of cytoplasm, we should expect them to indulge in their cytoplasmic activities at the expense of the normal cytoplasm of the cells of the fluids and tissues of the body. We should expect to find them active locally, generally, and possibly selectively robbing cytoplasm of electrons, lowering alkalinity leading possibly to acidosis, the formation of lactic acid, hydration, suboxidation and venous stasis. Such is the sequence and condition in some types of pathology at least.

By small doses of x rays I mean radiation of such wave length and frequency as will be absorbed by resonant electrons in the tissues, not materially disturbing those relatively stable electrons in normal tissues, yet at the same time striving to reestablish stable groupings in the atomic structure of pathological tissues, in other words accomplishing reversibility in reversible pathological cells. The irreversible cells are probably beyond our reach. Pathological cells are peculiarly sensitive to irradiations, and cells undergoing mitosis are conspicuously so. It is for this reason that small doses of x rays at short intervals are more effective than heavier doses at long intervals. Cumulative effects in such doses are highly improbable. In the bacteriological laboratory spores resist heat that kills more sensitive bacterial forms hence fractional sterilization for destruction, the antithesis of fractional radiation for reconstruction. This latter procedure is gaining many followers even in the treatment of malignancy.

When recovery takes place the tissues are soft, the cosmetic effects are good and the field lacks the fibrosis that goes with the destructive effects of heavy doses of x rays. The entire mechanism is different. This is demonstrable in the clearing up of suitable cases of socalled skin cancer of the face. In the problem of malignancy, Crile believes that the most dependable diagnostic procedure is the galvanometric investigation of the electrical potential of the tumor and Butts goes farther contending that in malignancy the potential is high and electropositive and he treats these cases with repeated small doses of x rays. W. L. Clark in suitable cases, employs small doses of x rays at short intervals, sometimes twice a day. While C. H. Mayo seems inclined to favor the bacterial factor in malignancy he takes into consideration the subatomic pathology as well.

In employing small doses of x rays for therapeutic purposes we are dealing with energy that is effective in the field of the subatomic structure of the tissue cells and in order skillfully and successfully to use this energy clinically we should study pathological conditions at a subatomic level as far as possible. To stress this point is the object of this paper.

That ultraviolet radiations may act upon pathological conditions indirectly has been shown by Rollier, who by exposing the feet and legs to an Alpine sun has noted improvement in lesions about the head.

Some twenty odd years ago while I was irradiating lymphadenomatous masses in the groins a recession was noted in similar untreated axillary growths.

It is important that every effective accepted procedure be practised clinically if indicated and I cannot stress too strongly colloidal medication, in suitable cases, for example, colloidal calcium and colloidal iodine intravenously. Calcium has been shown to have a regulatory action on the permeability of semipermeable membranes, raising the threshold and the potential in cell activities. Disturbances in calcium metabolism should be given careful consideration in many pathological conditions.

Professor Guido Holzknecht of Vienna bluntly states that almost all the beliefs and methods of the last ten years in radiotherapy have been proved incorrect. He believes in small doses of x rays frequently repeated in order to reach cells undergoing mitosis when they are particularly sensitive to radiations. He cites the experimental work on cancer in mice where single treatments resulted in no cures, while scattered applications secured cures in two out of three cases.

That the therapeutic possibilities of small doses of x rays are being recognized is shown by the voluminous literature of today covering practically all fields of medicine. While this procedure is not a cureall, it acts benignly in many conditions formerly beyond help, or sluggishly responsive to other methods of treatment.

In some pathological conditions the treatment is made more effective by the preliminary application of sedative conversive heat and the static condenser discharge, in other cases, utraviolet light is a helpful adjuvant to ionizing doses of x ray.

A few cases only will be cited to illustrate some responsive types and the technic employed.

HYPERTENSION

Case I.—Mrs. J. W. M., aged eighty; hypertension without demonstrable vascular changes. Systolic blood pressure 260, diastolic 90, pulse pressure 160, pulse 68. Technic: Nonmechanically rectified x ray machine, radiator type Coolidge tube. Fields of irradiation—centring on pituitary from four directions including thyroid, parathyroids, pineal, possibly thymus. Factors: 8 ma.; 50-60 K. V.; distance 24 inches; time 30 seconds each field; filtration 3 mm. of aluminum. The blood pressure fell quite abruptly; continued satisfactory after twenty treatments three times a week. June, 1922, systolic pressure 152; diastolic 65; pulse pressure 87; pulse 72. Abroad seven months without treatment. January 16, 1923, before treatment systolic pressure 156. November 25, 1924, systolic pressure 140; diastolic 70, pulse pressure 70. No other treatment except mild sedative autocondensation during autumn, 1924.

Case II.—Miss C. D. F., aged thirty-eight; hypertension following influenza in France, 1918. She had been gone over thoroughly elsewhere. Her tonsils had been removed. No appreciable impression had been made on blood pressure by any previous treatment. There was a probable endocrine disturbance. The patient was first seen on February 9, 1925. Blood pressure 232 systolic, 150 diastolic; pulse pressure 82, pulse rate 76. Arteries were soft. Ten treatments were given on consecutive days in series of five at a time; same technic as in Case I. Before the last treatment on March 16, 1925, the systolic pressure was 176, diastolic 100, pulse pressure 76. The patient is still under observation. Autocondensation acted unfavorably in this case. Treatment by x rays only.

TINNITUS

Case III.—Mrs. J. W. S., aged seventy-eight; tinnitus of five years' duration. Treatment was begun on March 9, 1923, using same technic as in Case II. Tinnitus disappeared after third treatment, with no return to date. X rays only were used.

Case IV.—H. L. W., aged sixty-one, duration of tinnitus twenty years off and on. Treatment on October 26, 1923, using same technic as in Case III. Tinnitus disappeared after second treatment; no return to date. X rays only were used.

OTOSCLEROSIS

Case V.—D. H., female, aged twenty; seen on November 2, 1922. She had been referred by a local competent aurist; diagnosis, otosclerosis. Same technic was used in treatment. A careful and conservative checkup was made by the aurist who reported at least twenty-five per cent. improvement. Patient is still under observation, and doing well. X rays only were used.

CHRONIC SUPPURATIVE OTITIS MEDIA

Case VI.—J. M., aged fourteen; seen on February 2, 1921. Both drums showed large perforations; there had been persistent suppuration in both ears for twelve years. He had been unable to attend school for the past three or four years on account of deafness. Same technic was used as in the other cases; suppuration ceased after the first week; no return. Reentered school within a month after beginning the treatment. Graduates from high school this spring (1925). X rays only were used.

CHRONIC CATARRHAL OTITIS MEDIA

Case VII.—L. J. W., aged fifty-one; duration of condition fifteen years. Clock, right ear ten inches, left ear two and a half inches; loud whisper, right ear five feet; left ear twenty-one inches. This patient had one treatment, June 26, 1922, and returned to his home in Detroit, where his aurist, noting the improvement in hearing (clock, right ear seventeen and one half inches, left ear four inches; loud whisper, right ear six feet, left ear thirty-five inches) tried to carry out the technic there without result. Patient returned on January 19, 1923, when the improvement noted continued on August 16, 1924, the last treatment, clock, right ear twenty-one inches, left ear five inches; soft whisper, right ear twenty feet; medium whisper, left ear twenty feet. He returns from time to time with the approval of his aurist.

ACUTE ECZEMA

Case VIII.—W. O. H., aged thirty-nine, a lawyer. The condition was of a few days' duration. Both hands, fingers, dorsum and palms were involved, with the usual severe acute symptoms. Sedative ultraviolet light, air cooled lamp at forty inches, was applied two minutes each to palm and dorsum. X ray used, with same factors as noted above except the time, which was one minute palmar, and one

minute dorsal exposure. Patient went into court after first treatment; his subjective symptoms had disappeared. He had a second similar treatment only. His recovery was prompt and complete. No other treatment was given.

INFANTILE PARALYSIS

CASE IX.—G. C., aged fifteen, duration of condition twelve years, involving anterior horns extensively, also upper and lower extremities and trunk. Sedative diathermy was applied to involved cord for elevation of temperature and arterial hyperemia; static condenser discharges for contractile effects, and ionizing doses of x ray; factors: five inch back up spark, eight inch target skin distance, one millimetre aluminum filter and a five milliampere minute dose. This patient was referred by a specialist and is checked up by him from time to time. Conspicuous improvement has been noted.

The importance of proper technic is well shown in Case VII. Faulty technic may bring no results. In modifying the technic, we shorten the wave lengths and increase the frequencies by increasing the voltage. When indicated I introduce a suitable foreign body into the field of the rays and in contact with the area to be treated in order to make use of the soft secondary radiations given off in situ.

Pfahler, Clark, Snow, Cook and others have long recognized the value of small doses of roentgen rays in treatment. While using x rays in treatment in the early days I observed repeatedly indirect effects which we could not then explain. Child's metabolic gradient conception throws light on this problem.

I am offering nothing particularly new in this brief paper. Much has been left practically untouched, oxidation, for example. My aim has been to stimulate interest in cytophysics and cytochemistry in pathology so that our technic may be bettered and the possibilities and limitations of this procdure may be recognized. The old adage, "While striving to help, be sure you don't hurt," has special significance in this field of work. I have given thousands of treatments during the past five years and have seen no recognizable ill effects in any case.

Treatment of Pneumonia by Diathermy*

WILLIAM BENHAM SNOW, M.D.
New York

The successful employment of diathermy in the treatment of pneumonia is based upon the effects of heat produced by that current in its passage through the tissues. That the current, in its passage, produces effects upon the metabolism of the cells other than the conceded effects of heat is probable; for, there are reflex effects from the administration which are attributable to heat applied at moderate temperature. The action of heat upon all tissues is to raise the local resistance together with depressing effects upon bacteria with degrees of heat not otherwise detrimental.

Nagelschmidt (1) showed that if strong currents of this character are passed through a solution of potassium iodide, no precipitate is thrown down, demonstrating the absence of electrolytic action.

DIATHERMY

Diathermy, the bipolar method of administering the d'Arsonval current, produces the local and constitutional effects of heat; the effects depending upon the sizes of the two electrodes, the current strength of the administration, the duration and the method of application. In the treatment of pneumonia with two electrodes of equal size placed at opposing sites, the skin toleration determines a safe degree of heat for passage through the intervening parts. This is easily effected with perfect control with modern apparatus, the socalled thermal penetration producing the characteristic effects of heat.

A skin tolerance of 105° to 106° F. and more is readily borne by all of the tissues beneath the surface. In the mucous cavities 115° F. may be administered without danger or discomfort.

It is not necessary to amplify on the importance of heat as a therapeutic measure before those who have made use of it, as all physicians do in one way or another. When, however, we consider its employment by the methods under consideration, we are entering upon a larger, more important use of heat than the older methods conceived. It has been shown that local applications of moist or dry heat at the surface, employing temperatures which can be tolerated, do not penetrate beneath the skin, and that reflected radiant light and heat penetrate, at best, but a limited distance to parts beneath the surface. A field of remarkable possibilities is opened with a measure which, when intelligently employed, will produce heat through the depths of the body without risk.

The physiological effects of heat, whenever applied to normal living tissue, is to increase the flux of blood to the part, producing hyperemia relative to the degrees of heat employed. This effect is in conformity with the normal reflexes provided to protect the tissues automatically from extremes of temperature.

In conformity with this law hyperemia occurs whenever heat is induced in normal tissue. This granted, it is conceded that whenever heat passes through disengorged tissues the increased flux of blood carries to the tissues an increase in nutrition, an increase in the number of leucocytes and metabolism is accelerated; all of which contributes to increase local tissue resistance.

In addition to these effects the tissues will with-

*Read by invitation before the Medical Association of the Greater City of New York, at the New York Academy of Medicine, December 17, 1923.

stand temperatures which will impair the development, lessen the virulence or destroy, in varying degrees, the existence of bacteria that are susceptible to relatively low temperatures, as are the gonococci. The germs of erysipelas yield to prolonged applications of reflected incandescent light, and middle ear infections to the same source of radiant light and heat.

As to the temperature which may be exerted during the passage of the direct d'Arsonval current—diathermy—it will vary with the resistance of the tissues, but will compare favorably with that of the skin vascularized by the action of the current. Most patients will tolerate at the surface a temperature of from 105° to 106° F.

Sternberg states (2), and is quoted by Hiss and Zinsser, that the pneumococci grow best in cultures at a temperature of 95° to 97.7° F., cease to grow at 104° F. in solid media and at 107° F., in fluid media, and are destroyed at a temperature of 125° F.

From these observations, it is apparent that with arrest of development of the pneumococci and increase in the phagocytic activity coincident with pneumonia, those conditions should contribute to the termination of the pneumonic processes, as it does in other pulmonic infections. This now seems to be justified by clinical experience as will be shown.

The value of diathermy in bronchitis has been demonstrated by ourselves and others, both by personal experiences, in the prompt relief from acute and chronic bronchitis. In the chronic cases, prolonged courses of treatment of from one to two months have been generally successful.

I have frequently stated that the time is coming when these conditions will not exist, because earlier and better management will exclude them; for as in pleurisy, it will be true of pneumonia; if treated before consolidation with the blood still in circulation, by the induction of hyperemia with the heat of diathermy and with the local increased phagocytosis it is possible to arrest the condition in the first stage.

Dr. Byron S. Price (3), first reported the use of thermopenetration or diathermy in the treatment of pneumonia as follows:

"During the stage of engorgement, and as well that of hepatization, however extensive, thermopenetration induced by proper quality of current gives prompt relief, both subjective and objective. Further, it is an active form of treatment which extensively decreases the mortality percentage. . . .

"The immediate effects are, marked diminution in dyspnea, cough, pain or distress, cyanosis and nervous excitability. Within a few minutes a tense and rapid pulse, as in asthenic cases, becomes much softer and slower, accompanied by slower and deeper respiration and the expectoration becomes more liquid and freer. The patient usually sleeps and rests comfortably after such treatment. He always asks for it to be given frequently.

"There is produced a more active phagocytosis and higher opsonic index with consequent inhibition of germ activity. Further, the degree of heat produced in the tissues, lessens the virulence of the cocci. As a result defervescence takes place by lysis."

The government hospitals have offered the best opportunity to demonstrate these methods, because they have the necessary apparatus at hand, as we regret to say, few other hospitals have.

It fell to Dr. Harry Eaton Stewart to verify further the value of diathermy in pneumonia at the Marine Hospital on Staten Island, where he is consultant in the department of physiotherapy.

The first ten cases treated under his direction at that hospital were reported in 1922, in a paper read before the American Electrotherapeutic Association (4).

The results reported in these cases, which were carefully tabulated with full case histories, were most encouraging if not conclusive.

In a recent monograph issued by Stewart (5), more cases of his own and others are reported which further demonstrate the value of diathermy in pneumonia. In this work, Stewart has given a scientific consideration of the methods of employing diathermy in pneumonia, and other inflammatory affections. In this work, he reports thirty-four cases of lobar pneumonia treated by diathermy in his service at U. S. Marine Hospital No. 21. In these cases there were seven deaths, death occurring in cases where there was little prospect of recovery from the outset. In one, in which five lobes were involved, treatment was begun on the third day. One case was complicated with empyema, another with bronchial asthma, another, in which the patient was fifty years old, with scoliosis and Wassermann four plus, and another with extreme hypotension.

Dr. Broeser and his associates reported thirty-one cases with but one death—a patient whose condition was complicated by chronic heart and kidney disease.

Of the cases reported by Stewart and Broeser, in but one was treatment begun on the first day, two on the second day, twenty on the third, thirteen on the fourth day, seven on the fifth, seven on the sixth day, seven on the seventh day, and one on the tenth day. The maximum current employed was 2,000 ma. and no reference was made to the sizes of electrodes. The average number of treatments administered was about six.

In all, sixty-seven cases had been reported as treated with diathermy with but eight deaths. As compared with controls computed by Stewart in his own cases, those treated by diathermy gave a mortality of 19.4 per cent.; whereas, the controls gave a mortality of 42.9 per cent.

When we analyze these figures, it must be acknowledged that treatment is beneficial when instituted after the third day, and that all cases terminated, as they did, by lysis and none as pneumonia regularly terminates by crisis. It must be conceded that the altered course was due to diathermy; and, furthermore, we may expect that when treatment is instituted during the first stage, before consolidation, that the mortality will be reduced to a minimum.

TREATMENT

High frequency transformers of adequate efficiency are now made by many manufacturers and consist essentially of a closed circuit transformer to step up the voltage, which is properly placed in circuit with two condensers, a d'Arsonval coil, a spark gap, and a hot wire meter. The multiple spark gap is a crowning feature of any apparatus of this kind.

The capacity of a capable apparatus should be

such as to deliver at least 3,000 ma. as measured by the hot wire meter, and more is often desirable. Such apparatus is adapted to both the alternating and direct current. When employed with the direct current, a rotary transformer is required to change the current to alternating. This is a matter of concern in a city like New York, where both currents are installed, requiring, with a portable apparatus that may be moved from place to place to patients' homes, a portable rotary transformer that will deliver 110 volts, otherwise, unless the apparatus is made especially to operate on a lower voltage, the output will be below the standard of requirement.

The electrodes may be made for use by the physician or his aides of sizes and shapes to meet the requirements of individual cases and conditions. They are made of soft composition metal or lead of thickness 22 B. and S. gauge, a standard which I introduced many years ago for static electrodes. Metals of that thickness keep their shape and do not become as wrinkled as does thin tinfoil.

We introduced the method of turning over the edges to give a rounded surface that would not discharge current from the margins as from a sharp edge of the metal, and so irritate or burn the skin. We leave a wide margin turned over at one end, to which we secure the clamp of the connecting cords that will securely hold it in place. This is important, as otherwise a dislodged terminal might cause a severe burn. The electrodes are thoroughly moistened and placed in close contact with the skin and must be firmly secured, so the patient can in no way remove them when the current is turned on, or a severe burn may be produced. The current should then be turned on slowly, taking from five to ten minutes to acquire the maximum temperature to be employed. During this time the patient should be instructed that the temperature over the whole surface should be the same. If there occurs a stinging sensation anywhere at the margin, or beneath the electrode, that pressure will not arrest, it will indicate that it is not in proper contact possibly from the presence of some object, as clothing or dressing beneath the metal, or that it is not properly moistened. It must then be removed and readjusted. Let the patient perfectly understand this, and if for any reason the surface is anesthetic, or the patient unconscious, observe the greater care.

These matters of technic are important, but require no more than ordinary foresight and attention to details with which all who employ diathermy should be familiar.

The familiar rule of doses of 100 ma., as measured with the hot water metre, to every square inch of surface, is a safe rule, but subject to some variation in cases with weak cardia or a sclerotic arterial condition. The usual rule that we employ, where it is desirable to exert a maximum heat effect for relief of the pains of pleurisy or in the early stage of pneumonia, is skin toleration.

The treatment of pneumonia by the administration of diathermy, either as an adjunct to other methods or as the main dependence, does not contraindicate the use of any other indicated measure, only as it renders their use unnecessary. Like heat, otherwise employed, it is congenerous with most methods.

In the first stage of pneumonia, with the usual severe pleuritic pains and chills before consolidation, it should abort the condition, from the point of view that the leucocytosis increased by heat should arrest the infection, when active circulation with hyperemia is so induced. It does this in acute pleurisy and acute general bronchitis, in our experience, without exception. The increased phagocytosis with increased flow of blood with the hyperemia induced by the heat, is an important factor in this stage, and if, as demonstrated in the laboratory, a temperature as low as 104° to 107° F. will arrest the development of the bacteria even lower temperatures would retard the growth. The leucocytes then complete the destruction and arrest the affection.

The clinical picture in the cases reported by Stewart and Broeser (6) and of the case that will be reported, seem to justify this assumption.

The second stage.—When consolidation has developed, as in all the cases reported by Stewart and Broeser, the histories recorded a most remarkable improvement. Every case in which recovery took place terminated by lysis and none by crisis.

This gave marked—I might say conclusive—evidence that the process was arrested either through the influence of the increased presence of leucocytes in the field, or the arrested development of the bacteria, or both.

As previously shown by the experiments of Sternberg, the development of the pneumococci is arrested in a solid media at 104° F.; so the current passed through a consolidated tissue which offered greater resistance to the passage of the current and exerted greater heat and so unfavorably affected germ activity. Be this as it may, the clinical picture is the same without reference to type.

In the advanced second stage, when the cardia shows marked signs of weakening, and cyanosis is present, as in the case here reported, the current should only be passed through the posterior cardiac space of both lungs or obliquely through the right lung, if affected, until the heart action improves, otherwise there will be danger of increasing the cyanosis. The narrow electrodes—four and a half by seven inches—should then be used and the treatments should be for shorter periods and more frequently repeated for approximately fifteen to twenty-five minutes and repeated every four to six hours.

The following case will illustrate most of the pertinent points of technic, and the progress of a case under treatment:

Case.—Dr. H. B. K., dentist, a transient in the city, was taken suddenly ill at a hotel Sunday evening, March 18, 1923. He was seen Sunday afternoon by the house physician who pronounced it to be a case of grippe with malaise and pains in the lower back with slight cough. Monday afternoon there developed in the patient a temperature of 104° F. with pain in the side when a diagnosis of pneumonia was made by the house physician. This was on March 19th.

The temperature, pulse and respiration from the 20th to the 23rd were continuously high, the temperature ranging from 103° to 106° F., the pulse from 112 to 140, and the respirations from 35 to 60.

On the morning of March 23d, I was called on by friends of the patient and requested to assist in the

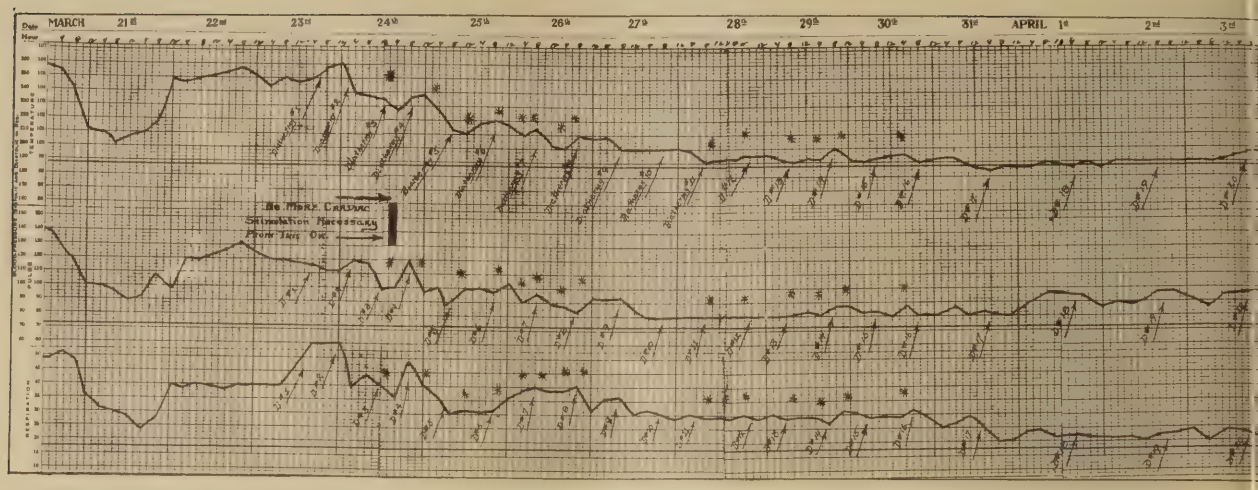

Fig. 1.—Chart of patient H. B. K., from first days of diathermy treatment to end of treatment. D, diathermy; *, Thermolite.

treatment of the case with diathermy. The patient's condition was otherwise considered to be hopeless. With the consent of the physician in charge we began the treatment. After some difficulty, we had the apparatus installed and on March 23rd the first treatment was instituted by my son whom I delegated to take charge of the case.

The patient was first seen in consultation with the hotel physician on the evening that treatment was instituted. At this time he was suffering from a case of type three pneumonia in the fifth day.

There was consolidation of the entire right lung and the lower lobe of the left lung. The patient was cyanotic, receiving inhalations of oxygen every half hour for ten minutes, and regularly digitalis and camphor in oil for stimulation. His temperature was then 104.2° F., pulse 120, and respiration 40.

The first treatment was given at 6 p. m. for twenty-five minutes, 1,500 ma. with electrodes four and a half by seven inches, laterally through the posterior cardiac space. At 8 p. m. the temperature was 105.6, pulse 112, respiration 60. At 12 p. m. the temperature was 106, pulse 112, respiration 60.

March 24th, sixth day, the treatment was administered at 4 a. m. as on the previous evening.

After treatment, temperature was 104, pulse 116, respiration 40. At 8 a. m., temperature was 104.8, pulse 116, respiration 48. At 12 m., temperature was 103.6, pulse 98, respiration 40.

Third treatment at 12 m. Same technic but prolonged to forty-five minutes. At 4 p. m., temperature was 102.6, pulse 100, respiration 36.

The patient was complaining of severe pleuritic pain, and instructions were given to get a therapeutic lamp (a Thermolite) and apply the reflected incandescent rays over the painful areas for at least one hour at a time or continuously, if necessary..

At 6 p. m. the fourth treatment was administered for forty-five minutes. At 8 p. m., temperature was 103.6, pulse 120, respiration 48. At 12 p. m., temperature was 103, pulse 98, respiration 40.

March 25th, seventh day.

At 4 a. m., temperature was 102.6, pulse 100, respiration 36. Pleuritic pains were greatly moderated and the quality of the pulse was greatly improved. Treatments from this time were given for one hour each. At 8 a. m., temperature was 101.1, pulse 90, respiration 30. At 12 m., temperature was 101, pulse 100, respiration 32. At 4 p. m., temperature was 101.4, pulse 101, respiration 30.

At 7 p. m. treatment was given anteroposteriorly through the base of the right lung for one hour. At 8 p. m., temperature was 102, pulse 98, respiration 32. At 12 p. m., temperature was 101.8, pulse 104, respiration 36.

March 26th, eighth day in bed.

At 4 a. m., temperature 101, pulse 90, respiration 40. From noon March 25th, or after the fourth treatment with diathermy, no cardiac stimulants were given. This was undoubtedly due in part to the administrations of reflected incandescent light, which has been demonstrated to produce remarkable reflex clinical effects upon the cardiac centres in pneumonia and other depressed cardiac conditions.

On March 29th at 8 a. m., the patient had fluid at both bases, which was completely dissipated by two diathermy treatments.

From this point on, the patient made an uneventful recovery, two diathermy treatments being given daily over different parts of the chest as indicated.

On April 2nd, the patient felt well, but complained of a husky voice. One diathermy treatment anteroposteriorly through the larynx cleared this up.

The patient was discharged on April 3rd. The temperature was 98.6°, pulse 80, respiration 24.

CONCLUSIONS

1. Diathermy when skillfully administered in pneumonia with due regard to existing conditions is devoid of all danger, always a synergist, and never an antagonist to other measures.

2. Heat employed as a therapeutic measure increases local tissue resistance because the normal reflexes respond with an increased influx of arterial blood into the part, increasing phagocytes and improving nutrition and local metabolism.

3. Diathermy is the only measure that will induce heat with safety and uniformity through the body between two equal surface contacts. When so applied, it renders an exceptional service in the treatment of infectious conditions, and is unlimited in its indications, except over walled in pus cavities.

4. In all acute pulmonary conditions and early phthisis, it plays an invaluable rôle, in accord with the recognized therapy of heat.

Electrotherapeutics in Urology*

VICTOR C. PEDERSEN, M.D.
New York

Space makes it impossible to embrace more than a few of the important points. But the following headings may be worth while to the reader. In the transition from doubt concerning the value of physical measures of treatment to a reasonable acceptance of them, certain salient elements must be recognized. Diagnosis must be valued in terms of method conceived, improved, and universally applied as in the modern cystoscopic procedures of urology; and therapeutic values must be accepted as applied to special forms of treatment in electrotherapy and other physical treatment. Perhaps the shortest method of realizing these facts is a survey of any decade in medicine along the accomplishments of diagnosis and treatment. If during the last thirty years we compare the middle decade with the first and the last, one realizes instantly what is meant. Each decade may be compared to the disadvantage of the next preceding, but to the advantages of the next succeeding ten years.

In diagnosis in urology the cystoscope is absolutely essential. In fact, if we had to discard the one or the other in any arbitrary sense, the cystoscope would be retained whereas the x ray would be rejected. No lesion having bladder symptoms should be diagnosed without a cystoscopy, and no kidney case without a catheterization of the ureters. If the prostate is involved, the lobe or lobes chiefly in trouble must be recognized and measured, and a comparison made between the vesical and the rectal protrusion. The patency of the urethra is of extreme importance and here a peculiar fact familiar to urologists is still to be recognized by electrotherapeutists. This is that a middle lobe may obstruct the urethra so that the residual urine is large and yet the urethra seems to be patent to any usual instrument. The latter is an incident dependent on the fact that the middle lobe is pushed back or to the side by the penetrating instrument as long as it is relatively small and soft. The cystoscopist judges the meaning of such a middle lobe by the effect of its obstruction on the bladder, such as trabeculation and sacculation, increase or alteration in residual urine. Infections in the upper urinary tract are very easily demonstrated and measured and are of the most inevitable importance. It is useless to treat the bladder and the prostate if the real source of the pus is in one kidney or other.

In addition to these basic axioms for the electrotherapeutist there are two others which will always lead to failure if disobeyed. These are that where pus is retained surgical evacuation must be secured, and that where obstruction exists surgical relief of it must be given. If these time honored laws are disobeyed by the electrotherapeutist, then his treatment is futile, unscientific, and unprofessional because unjust to the patient.

The urologist must recognize that like the majority of other methods of treatment, physical measures aim to produce improvement in circulation directly and fundamentally. In other words, in rather certain measure hyperemia is the outcome. As long ago as 1905, Bier (1) had shown rather well that hyperemia possesses analgesic, bactericidal, absorptive, solvent, and nutritive effects. Bier's methods resulted usually in a congestion or venastasis rather than a constructive arterial hyperemia. Hence, in large measure many of his methods have been abandoned. Electrical methods on the other hand, of which diathermy is the predominating type, cause an arterial hyperemia which immediately has the opposite effect of a venous stasis, namely, active nutritional results.

An example of the meaning of proper diagnosis in prostatic cases and the recognition of obstruction, it is worth while outlining a case which was under my care jointly with one of the electrotherapeutists. The latter did not understand the tremendous influence of the obstruction of the middle lobe, which caused an increase in the residual urine from nine ounces, measured, while the patient was in my hands for four months, to about fourteen ounces, measured, a short time after the patient was resigned to the sole care of the electrotherapeutist. It is not possible to say exactly what happened, but attempts to pass full sized catheters probably caused the middle lobe to become edematous, and thus by adding to the obstruction, increased the residual urine. Without cystoscopy, one must rely on subjective symptoms which are always the least reliable and on rectal protrusions which may be very little when compared to obstruction of the bladder neck. Obstruction is the supreme single factor, because our bladder walls were never meant to overcome obstruction, and if the obstruction is maintained the muscle hypertrophies, trabeculates, sacculates, atrophies, and finally is practically paralyzed. Long before the period of inertia is reached ascending infection of the kidney occurs through those changes in the urine which begin with decomposition of chemical type and end with decomposition of bacterial type.

Another case illustrating the inertia of electrotherapeutists is that of a gentleman with a very large prostate, much residual urine, and a septic bladder. The patient refused operation, so that only palliative measures were possible. The patient was turned over to me by one of my colleagues during his vacation. When I reached the bedside, the bladder was above the umbilicus, and the patient so septic that he was delirious. The family physician had not passed the catheter because the electrotherapeutists had forbidden it. My reply was no matter what might have been behind such a strange opinion, I would immediately pass the catheter and empty the bladder on the simple principle that where there is septic material it should be evacuated. I slowly drew off more than a quart of foul infected urine,

*Read before the Philadelphia Electrotherapeutic Society, February 4, 1925.

washed out the bladder, directed the family physician to repeat the process every eight hours, and was pleased to see the patient's delirium relieved in about thirty-six hours. There is really no excuse for so foolish a refusal to follow the simple principles of surgery.

That the urologists are beginning to realize the value of various electric methods is shown by their tendency to adopt them. This situation is one of promise and satisfaction. Those of us who are great in the science of medicine should adopt anything and everything that is good. Long treatments of twenty, thirty and forty minutes are the ones which produce the results. During the period of lowest resistance, it is probable that daily treatments are most advisable. For example, one of my friends in the insurance compensation field has found that a daily radiant light treatment in indolent cases will maintain the rate of healing very much better than every other day, although each session may be a half hour long. The physiological results are more important than metre indications, and in diathermy they are more important than thermometer indications because a thermometer cannot possibly reach wherever the current passes. Subjective sensations are important. Those which the patient feels very definitely and may complain about especially if followed by a reaction after treatment usually indicate a current so strong that it is apt to defeat its own object. Conversely, a current which the patient does not feel except to describe it as soothing is the very one which is going to do the good.

The urological lesions which are somewhat amenable to electrotherapeutic measures are comprised in the fully accepted classifications of congestions, inflammations, abscesses, benign neoplasms, malign neoplasms, and calculus, as these affect the urethra, bladder, ureters, kidneys, prostate, vasa, seminal vesicles, and testicles. It is necessary to confine much of the following data to the male subject, on the ground that the other paper of the evening by Dr. Barton Cook Hirst is concerned in the female subject.

URETHRA

Infections causing infiammation of the male urethra are exceedingly common and probably comprise a large number of cases available for study. For several years I have been studying and am still studying the results of Ballinger's sealing in method with very satisfactory results, especially when the patient is seen within twenty-four, forty-eight or seventy-two hours after the first possible sign of discharge. The earlier cases are far the most favorable. Therefore, as yet I have not studied the use of diathermy in these acute cases. Corbus (2) states that the patient should present himself within seventy-two hours of the infection, the diagnosis must be bacteriologically determined, and the first urine clear or slightly turbid. The patient is placed on the autocondensation couch. A sterile urethral electrode is lubricated and passed for three centimetres, secured against slipping and when the patient is relaxed the current is slowly turned on and increased to 110° F. and maintained at this point for forty minutes. The current is then slowly turned off. After rest, the instrument is passed for the full length of the anterior urethra and the same procedure followed. The treatment should be and usually is entirely painless. If gonococci are present the following day two more treatments are given. If they are absent during the following three days a mild hand injection is prescribed. If they are absent for one week, cure is established. This method is interesting because it begins and ends with bacteriological examination. A question arising is whether it is the thermometric heat which does the work, as much as those biochemical influences of the current which extend beyond the sphere of the thermometer and offer no means of measurement within our present knowledge. In a certain sense the method seems to be efficient only toward gonococcal acute urethritis. We need equally to apply it or an analogous method to the bacterial nongonococcal acute urethrites which are equally troublesome in many cases. I have repeated the following scientific fact (3) before this society on other occasions, and will do so again now on the ground that it is entirely too little before the minds of physicians who are not urologists.

"The organisms which cause bacterial nongonococcal acute urethritis are streptococci, staphylococci, pseudodiphtheria bacilli and Bacillus coli communis in the pyogenic lesions, Micrococcus catarrhalis in the true catarrhal inflammations, Treponema pallidum in syphilitic and Bacillus ducreyi in chancroidal, and various organisms in herpetic urethritis. Luys (4) on this subject says that the most important are the streptococcus, staphylococcus, pneumococcus, Micrococcus fullax, Micrococcus pyogenes aureus, Micrococcus cereus albus, Bacillus typhosus, Bacillus coli communis, Bacillus diphtheriæ, Bacillus tuberculosis, and various sarcinæ. A small, thin bacillus in chains and clumps is, according to Finger (5), Adrian (6), referred to by Luys (4), the common saprophyte of the prepuce and very often in the urethra in longstanding cases. Moscato (7) reports a case of urethritis accompanying every attack of intermittent fever."

In periurethritis and folliculitis diathermy again is of value either in germicidal dose producing a temperature of 110° F., or in nutritional dose augmenting the normal hyperemia of the part and thus restoring it. Where pus is retained in any of the follicles or abscesses, surgical evacuation must be practised, unless as claimed the relaxing influence of diathermy opens up the obstructed duct.

Stricture is best treated with the negative pole of the galvanic current. The smaller the stricture the less potent the current on the ground that the smaller size of the bougie against the face of such a stricture causes the current to heap up on it, and thus to become locally too strong. Thus for a size 16 French stricture five ma. of current would not be too great, but the same current for an obstruction of 6 French calibre might be too great. For so small an instrument two or three ma. are sufficient. In the past, all the difficulties and errors in the treatment of these lesions with galvanism have arisen from the fact that the positive pole, which is irritating and caustic, and not the negative pole, which is soothing and relaxing, was used. Therefore, no one should attempt to use galvanism without being in possession of a polarity indicator. Occasionally the public utilities corporation will change their polarity in the main stations during repairs, making no difference whatever in the

lighting and power service in homes and factories but making tremendous difference in electrotherapeutic work. Diathermy may be used in stricture cases but always with great caution, and preferably only after the calibre has been restored to a large diameter and then with the purpose of assisting in absorption of the congestion and infiltration around and beyond the fibrous band themselves. The reason is at once obvious. The smaller the electrodes in diathermy the greater the danger of rather sudden overheating with tremendous and penetrating caustic effect. Such an influence is the last of all desired in this class of work.

In posterior chronic urethritis with granulations, ionization is of great value and may indeed be superior to the majority of other methods. The aim is to deposit oxychloride of the metal used within and through the depths of the mucosa. If relaxation is required the negative pole is employed, whereas if stimulation is desired, the positive pole. For mild influence, the electrode is made of chemically pure zinc and for more potent influence of chemically pure copper. Accordingly, oxychloride of zinc or copper is deposited in the depth of the mucosa for approximately five tenths c.m. In raw meat, such a penetration is readily obtainable. Owing to circulatory activities, it is probably somewhat less in the living subject. A current of not over three ma. is employed for not more than five minutes. A detail which must never be omitted is that if the positive pole has been used, the polarity must be reversed so as to cause the mucosa to come away from the instrument by the relaxing influence of the negative pole, otherwise the trauma of tearing off these adhesions will commonly do more harm than the ionization did good. Owing to difficulty and delicacy. ionization should be the last modality employed until all others have been very thoroughly mastered.

The testes, vasa, and seminal vesicles are next in order for consideration. It is said that in the army hospitals having electrotherapeutic apparatus available, diathermy was so comforting to the soldiers that they usually asked for it during the various forms of orchitis. One may adopt special instruments such as that of Corbus, consisting of a scissor-like handle of fibre carrying two oval cups for grasping the testicle. I have preferred a less direct and somewhat safer method of passing the current. A large distributing electrode is under the buttocks while the testicle is covered with a mass of wire mesh thoroughly soaped, and held in place with a light sandbag in the hand of the patient. The testicle is kept from slipping either by the aid of a Bellevue bridge or that which works equally well, the thighs of the patient closely crossed so that the gland rests between them. Corbus recommends turning the current slowly on until cutaneous discomfort is noticed and then slowly off until this discomfort disappears. I prefer much milder current, hardly over 300 ma. maintained for a long period of time, hardly less than three quarters of an hour. In one or two cases disturbance has followed a current of 750 ma. whose heat the patient noticed but did not complain about. Correlated with diathermy in these cases should be radiant light and the high vacuum glass electrode attached to the negative pole of the high speed multiple plate static machine or to the Oudin terminal of the high frequency machine. The condenser discharge glass electrode may be used in much the same way as a means of sparking the skin as a counterirritant. Finally the brush discharge attached to the negative pole of the static machine or the de Kraft brush discharge attached to the high-frequency machine may be tried within tolerance of the skin also as a counterirritant. In funiculitis all the foregoing methods may be employed, usually almost with wonderful benefit. Diathermy may be employed by using a relatively small band of soft metal along the course of the vas attached to one pole while the distributing electrode is under the buttocks. In this way the current will be heaped up within the inguinal canal for localizing the benefit, but caution must be exercised not to provoke a burn along the canal.

The seminal vesicles carry us into the interior of the body, and they add to the complexity of our problem through the determination of retention or drainage of pus. The author feels that none of this work should be undertaken except after a complete diagnosis by a urologist, because even that is by no means infallible but it is far less fallible than old-fashioned guesswork. In these cases the seven glass test of the author is par excellence the best single procedure. When in doubt, it is far better to leave any case alone so far as energetic localized treatment is concerned with any method whatsoever. Rest in bed with the ice cap if well borne, hot sitting baths, and radiant light comprise the best management, and hardly, if ever, may be held indirectly responsible for extension of the disease to the opposite side and to one or both testicles.

My reasons for caution are illustrated by the following two cases. During a vacation I referred to one of our best electrotherapeutists, a man who had a chronic discharging abscess of the prostate and declining bilateral seminal vesiculitis. One testicle had already been removed through damage to it earlier in the disease. The gonococcus was not discoverable even after a cautious seven glass test. Written requests were disregarded to the effect that the mildest possible treatment be given and that if the static wave current be used at all the gap be maintained at less than a half inch. Instead of this a three inch gap was used, and discomfort beginning during the treatment rapidly augmented and finally appeared as involvement of the other testicle which had to be removed, according to the judgment of the general surgeon who had charge of the case after he returned to one of our suburbs. The judgment from which the treatment sprang was improper, because it led to the taking of chances in the presence of pus.

The other case occurred in a young man having a relaxed prostate owing to the irritation of engagement to be married. The seven glass test did not demonstrate any important organisms in the opinion of the laboratory. After considerable treatment with all the ordinary methods, the static wave current was begun with a narrow gap and at the third or fourth treatment advanced to a three inch gap without discomfort to the patient. The metronome interruption was used. About five days after this particular treatment one testicle began to swell and pass through the entire course of this complication. Ultimately both of these cases reveal the tremendous importance

of gentle methods in the presence of organisms, even though they do not appear to be active. The final result was that both these patients left my care and no doubt are blaming me roundly for everything that occurred.

For these lesions during the subacute and chronic periods the high vacuum glass electrode attached to the negative pole of the static machine, positive pole grounded, spark gap one inch, one to two ma. of current is through its actinic and mild x ray effect of great benefit. Much the same result is obtained through the Oudin terminal of the high frequency machine provided the tube is not allowed to heat up more than within the gentle comfort of the patient. The controller is rarely opened beyond the first or second terminals, and the gap should be just sufficient to activate the tube regularly. After infection is over, the static wave current may be tried, but always with the preference of error on the side of too small a current in accordance with the foregoing two case reports. Almost all these patients are the victims of a granular posterior chronic urethritis for which ionization should be used among other methods, as previously described.

The bladder is the next organ in our ascent to the kidneys, and we come prominently upon cystitis and pericystitis. I have heard a number of electrotherapeutists utter the remarkable statement that it is not necessary to irrigate the bladder. This is definitely wrong. The viscus must have as clean a mucosa as possible, no matter whether topical applications are to be made as mild antiseptics retained for a half hour, or whether electrotherapeutic measures are to be attempted. The return fluid should be as clear as it enters to the naked eye in an ordinary glass. In chronic cases often the fluid is clear except for a scattering half dozen shreds which frequently cannot be totally removed until the patient is nearly well. Inasmuch as the decomposition of urine in the bladder preceeds bacterial invasion, cleanliness secured in this way is supremely necessary. Also, as a preventive of the appearance of bacteria or as a potent means of removing them urinary antiseptics are essential. The formaldehyde group typified by hexamethylenamine are among the best. Four practical points are commonly overlooked. 1. Unless formaldehyde is found in the urine after two or three days, the particular patient is not splitting off this radical and is therefore not obtaining much value from the drug. Change to benzoate of soda or acid phosphate of soda is in such patients in order. 2. The converse is more likely to happen. The splitting up is so rapidly done that the formaldehyde overdoes its function, attacks the kidneys, or the surface of the bladder, and causes a chemical inflammation which in the case of the kidney may be hemorrhagic and in the case of the bladder may be a violent and painful cystitis. Hence, during the first two weeks of administration, the urine should also be examined for signs of irritation, such as desquamating epithelium, blood cells, especially red, and casts. If these occur in alarming numbers then the dose must be reduced or the drug changed. 3. Prolonged administration of the formaldehyde group should always be broken by periods of rest. Inertness of the medicine soon supervenes or accumulation occurs with the foregoing irritation. I prefer to omit the medicine on Wednesdays or Sundays, or both. Some authorities alternate the formaldehyde drug with another antiseptic every week from week to week, so that out of four weeks two are covered by the formaldehyde and the other two by the other drug. 4. Corrigents of many of these difficulties as well as adjuvants of the action of the formaldehyde group are such drugs as benzoate of soda and the acid phosphate of soda. The patient may be given two prescriptions to alternate by the week or by the fortnight, one containing equal quantities of the formaldehyde drug and benzoate of soda, and the other containing the formaldehyde drug with acid phosphate of soda. Such a balance in medication grants to the patient through the electrotherapeutist the knowledge of years of study by urologists. Omission of these details is not just to the patient. The indication is to decongest the inflamed area within or around the bladder. Heat is preeminently the decongesting medium, and for cases in which the oldfashioned sitzbath was available, diathermy or radiant light may be used. Diathermy quiets the circulation by causing arterial activity and relaxes the smooth muscle fiber. Both actions tend to be antispasmodic. Radiant light draws the blood from the deeper parts into the skin of the abdomen or buttocks and perineum, and further has an influence called actinic whose value is great, but whose exact nature is most difficult to explain. The germicidal and actinic influences of x ray undoubtedly have a place in deeply seated infections, such as those of the bladder and perivesical spaces.

After the infection has been brought under control, more or less completely, and organisms are difficult to find, the atony of the muscularis must have attention. In no circumstances should stimulation of the muscularis occur during acute cystitis for the very reason that these patients are best in bed and quiet. When the chronic period is present, interrupted galvanism, sinusoidalism, static wave and faradism may be employed. Always beginning with mild current, slowly ascending to tolerance and never causing irritating reaction. The bladder must always be emptied first. In other words, these artificially induced muscular activities must never work against incompressible urine retained in the bladder either through muscular spasm at the neck, or through obstruction as in prostatic disease. Galvanism is applied with much the same purposes and precautions as used by neurologists with success in neuritis, paralysis and surgical injuries in the treatment of muscles. The galvanic current may be interrupted with the finger or mechanically. If sinusoidalism is used, it is well to have the sine wave correspond with the pulse rate or a multiple or prime factor thereof so that the electrical force will not run counter to the general phenomena of the blood stream. Faradism seems to offer much in stimulating an atonic bladder or an atonic sphincter, especially after postoperative conditions. In the same way the static wave current with gap just sufficient to produce a sensation of muscular contraction may be applied alternatingly. At one session the pad may be placed over the bladder and at another session on the spine in the region of the vesical and rectal centers. As just stated, the muscularis must not

contract on an incompressible immobile mass of urine. Pain during or after the application means reduction in the strength of the treatment or even cessation, because the effect is then that of another spasm. If the inflammation lights up the treatment should cease or be changed to a more sedative quality such as the x ray. Adhesions yield to diathermy chiefly through the sedation of chronic congestion and the nutrition of arterial stimulation. Negative galvanism and the mild static wave are of importance. In contracture of the bladder, as after tuberculosis, diathermy allied to and combined with other methods is often of great service, but the pad under the buttocks and that over the bladder should be large so as to include all the surrounding tissue and so as to permit the use of large milliamperage, not less than 1,000 ma. Although the patient does not feel this current, its action is positive and beneficent.

Ureters and kidneys.—Diathermy is heat by conversion within the tissues arising from resistance to the passage of the electrical current. This is far different from ionic movement within the tissues, such as some authors claim to be the underlying basis. We have to distinguish the nonsurgical or medical cases and the suppurative lesions. In addition to the various dietetic and medicinal measures decongestion of the nonsurgical nephritis is the aim. This may be accomplished by heat through radiant light baths, the Turkish bath, and diathermy as examples. One of the most important things is that general diathermy through the autocondensation couch vastly increases elimination. Titus has shown that sweating of the skin and augmentation of the total solids in the urine, which is increased in quantity, are common results. All elimination seems to be improved. Occasionally one sees patients who probably would not be benefited by any treatment in whom diathermy fails. One patient, for example, passed through a pneumonia in the midst of a long continued albuminuria, which nothing totally abolished. Mild diathermy passed directly through the kidney between two circular five inch electrodes definitely made the albuminuria worse, and had to be abandoned. A similar result followed the use of diathermy through both kidneys with a very large chain mesh electrode on the abdomen and the patient lying on an autocondensation couch. On the other hand, the use of the deKraft autocondensation chair helped the patient, but did not totally relieve the albumin in the urine. In the suppurative lesions, such as stone and pyelitis, if only drainage is complete, benefit may be secured and is often most satisfactory. Accurate laboratory investigations must be carried out in these cases for definite conclusions, and exact comparisons with the results of other measures. Here again if electrotherapeutists guess at pathogenetic data and results their work would be discarded by urologists and will richly deserve such discard. With the modern methods of penetrating the kidneys now so safe that pyelograms may be done in the midst of hemorrhage, it is almost foolish to talk of the dangers of this work unless the urologist doing it is a tyro. I have a patient with double complete ureter with four outlets, an infection of both pelves with the Bacillus coli, and a history of removal of stone. The very measures which failed in the foregoing case of medical nephritis have practically restored this patient to health.

Diathermy may be gently used for a very short period to be followed with definitely gentle application of the static wave current, radiant light, and x ray. It is well known that in tuberculosis of the lungs diathermy may cause a severe hemorrhage either by the general congested action of the current or by the presence of an ulcerating tubercle near a bloodvessel which under the influence of the congestion opens into the ulcer and bleeds. The same result is to be expected in tuberculosis of the urinary tract, and doubtless as diathermy is used more and more by urologists, incidents of this kind will be reported in literature. Nevertheless, diathermy should not be condemned, but contrariwise used with greater caution. Conversely, however, reliance on diathermy alone is not sufficient. Valuable as it is, one of its chief functions is to prepare the way for the greater activity of other methods. Similar to the benefit of a general massage treatment of elimination, the general autocondensation treatment must never be neglected.

Prostatism comprises congestion, inflammation, abscess, hypertrophy, neoplasm and calculus. Surgical intervention must be had for abscess, neoplasm, and calculus to which electrotherapeutics may be a very good preliminary and subsequent adjuvant. The retained pus of abscess is definitely dangerous from absorption and according to rule must be evacuated, and as calculi in the prostate both originate in and are accompanied by pus they must come within the same category. This paper does not aim to take up the surgical treatment of neoplasm, typified particularly by the later methods of surgical diathermy. X ray and radium in the preliminary periods of the treatment and after the removal of the main tumor are both of great value. In hypertrophy the detail of obstruction to the outflow of the urine measured in terms of residual urine, and the tendency to decomposition and bacterial cystitis are the real deciding factors as to what shall be done. A residual urine of as little as two drachms, which is constant and increasing and shows a tendency to infection, demonstrates the needs of removing the obstruction according to the surgical rule already laid down with regard to all obstruction. This is particularly true if there is the slightest tendency toward involvement of the kidneys which may proceed not only from the ascent of the infection from the bladder but also from filtration of bacteria from the blood current into which they enter from the intestines. Most of these old patients are constipated naturally through age and the weight of the enlarged prostate on the rectum causes an obstipation. Hence one sees Bacillus coli cystitis, and pyelitis suddenly arising out of a perfectly clear sky of reasonably good health without the slightest instrumentation having been practised. Such incidents explain why prostatics with obstruction and residual urine will remain in reasonably good health until they suddenly appear totally unable to urinate and with a cystitis well established.

The seven glass test may be judiciously used in patients with moderate obstruction because it not only gives a primary index of the urinary system

from the bladder upward and of the sexual system from the bladder downward, but it tends to prove the presence or absence of pus in the prostate itself and in the seminal vesicles themselves. In the non-obstructive prostate, characterized chiefly by congestion with moderate hypertrophy indeed and as a preliminary to other treatment of the more profound cases with obstruction, we have a proper relation and alternation between the high vacuum glass electrode attached to the negative pole of the high speed static machine, the condensor-discharge electrode, radiant light, the static wave, and x ray. The principle should be laid down and obediently followed that if the response to these measures is not prompt and progressive, especially as measured by an improvement in the residual urine, it is far better to turn these patients over to surgical intervention before the obstruction reaches so high a degree that the mucosa and the muscularis of the bladder begin to undergo manifest changes. In the remote past of prostatic work arising from inexperience at that time, many unfavorable terminal results arose from the fact that the average subject had already advanced far in the destruction of the bladder mucosa by cystitis and in the weakening of the bladder wall by trabeculations, sacculations and atony. Today, operations are done before any of these conditions are more than suggested, and always before they are fully established. Failures only are seen when the patient refuses operation or when a member of the general profession does not appreciate the importance of the symptoms as they are. Too much caution cannot be enforced upon the minds of the electrotherapeutists that penetration of the bladder with a catheter without much difficulty is by no means proof of the absence of obstruction in the face of a persistantly rising and decomposing residual urine. The passage of the catheter is an artificial test, whereas the real condition is physiological incapacity of the bladder to overcome the obstruction which may take almost any form and degree regarded from inside the bladder and working toward the outer world. With regard to pus in the prostate, allusion is again worth while to the two cases reported in the forepart of this paper, of patients in whom acute epididymitis was directly induced by the application of the static wave current.

In my own practice the best results in prostatic work have been seen in the group of cases in which congestion is a predominating factor, grafted on underlying simple hypertrophy and in postoperative states. I am by no means convinced that electrotherapeutic measures can be applied with even reasonable hope of stopping the onward progress of a real hypertrophy in any material degree. As a rule, the tendency toward advance in the obstruction changes in the urine, serious alterations in the bladder, involvement of the kidneys, progress more rapidly than the gland as such responds to the treatment. These statements do not mean that electrotherapeutic measures as applied to the prostate should be abandoned but that they should be applied to a group of cases seen earlier than most of us reach the patient. I have two patients now in hand in whom the prostatic lesions are so early that it is almost possible to promise so great a correction of the process that operation may be indefinitely postponed. Time alone will tell in cases of this type. The brother in law of one of these patients has had one attack of inability to urinate so as to require catheterization, but he steadfastly refuses my request to come for a full examination. In the end he may duplicate the experience of another man who three years ago was asked to report for investigation during what seemingly was very early signs of oncoming hypertrophy. In this brief period when he did come he had a middle lobe as large as a seckel pear totally obstructing the outflow of the urine and a prostate which when removed had to be crowded into an eight ounce jar. With perfect function restored to his bladder neck, this man still has bladder symptoms because of the changes in the mucosa and the muscularis during those three years. There is one type of prostate which may be benefited rather definitely by electrotherapeutics if the obstruction is not great—the fibrous, contracting prostate. It is possible that negative galvanism in rather free but judicious doses may relax this mass of fibrous tissue materially much as negative galvanism relaxes a stricture of the urethra. I have been patiently waiting for a suitable case in which operation has been refused in order to try this method perseveringly. An obstacle is the fact that most of these fibrous cases have severe and painful obstruction and are very glad indeed to have it surgically removed.

ARTHRITIS

Lovett (8) notes the following forms of joint lesion: "1, Arthralgia without definite joint lesions; 2, acute serous synovitis with much periarticular swelling; 3, acute fibrinous or plastic synovitis, with little effusion; 4, chronic serous or purulent synovitis; 5, periarticular involvement, such as bursitis and tenosynovitis. Whatever the classification, all forms may merge one into the other, without great demarcation." Unless the diagnosis along these lines is established, exceedingly favorable results will be claimed in patients for whom in a sense the wrong diagnosis has been made. Again we are thrown back to agreement by electrotherapeutists with the diagnostic standards of other lines of medicine, otherwise their results will be challenged and that with great justice. The various means must be used in correlation and faith should not be pinned on one method alone. Diathermy may be run through and through the joint from side to side in a direct line or obliquely by having one electrode on the front part of the thigh and the other on the calf or conversely, one on the shin and the other on the back of the calf. Or cuffs may be passed round and round the thigh quite a distance above the knee, and round and round the calf an equal distance below it. Inasmuch as the muscle substance is very apt to be inflamed also, it is exceedingly advisable to include as much of the musculature around a joint in the path of the current as possible. Hydrotherapeutic methods must not be neglected, and other modalities, such as radiant light, are of great service. Stimulation in the form of the static or deKraft's high frequency brush discharge or Travell's brush discharge from the positive pole are of great value, likewise sparking from the static machine and the various forms of high vacuum or condensing discharge glass bulb

electrodes. Massage in these cases and passive motion are important. When motion becomes possible, then the static wave, galvanism, faradism and sinusoidalism may be applied to the muscles.

FUNCTIONAL DISORDERS

Few cases in urology cause more vexation than the patient with functional disorders, especially exemplified by sexual impotence. The basis of treatment must be a full determination of the underlying cause. In this point is a statement recently made to me by the physician of a certain large hotel who happens to see a great number of these patients. He gave as his opinion that electrotherapeutics have only a psychic or imaginary influence and never a definite physical one. The error in diagnosis is so wide in its range that there is small wonder indeed that the results have not been favorable. I have recently evolved the following sequence for the treatment of impotence. Two patients now under care are responding well. It is to be noted that the high frequency and other forms of current are used together, and that all avenues for treating the prostate are used and that the nervous system is reached through the spine. Finally, attention at home is not neglected. A, diathermy—prostate (rectal) 300-400 ma., 1, oudin and 2, static wave; B, diathermy—prostate (urethral) 200-300 ma., 1, oudin, 2, faradic surge; C, diathermy—spine, 1, galvanic sinusoidal, 2, phototherapy, 2, static wave; D, at home—cold douches or sponges to the spinal column.

CONCLUSIONS

Electrotherapy is not absolutely infallible. Anyone undertaking application thereof with such enthusiasm will certainly be disappointed. Its application is limited and in many instances the results are contradictory. Whenever unusually good results are expected they are not forthcoming, and when negative or disappointing results are rather in the order of events, the contrary may be seen. The real points to remember are that the apparatus now available is suitable for real progress and if distinctions in physical actions are known and proved, and if diagnoses are accurately made, then a common ground is reached from which real deductions may be drawn. As the author has said elsewhere: "There are a few basic principles which are altogether too often neglected. The patient must not be hurt or frightened; electrotherapy must be employed to augment all other measures and not neccesarily to supplant any; the current must produce profound circulatory effect of creative character and it must be opposed to the circulatory condition of indolent character due to disease; the modalities must be varied influences and finally the electrotherapeutic measures must leave no evil aftereffects. If these principles are obeyed little trouble will be met.

Electrotherapy in Paralysis Following Peripheral Nerve Lesions and Poliomyelitis*

RICHARD KOVACS, M.D.
New York

The application of the advanced methods of physical therapy, especially electrotherapy to the manifold nerve injuries of civil life, is a logical sequence of the important advances in the field of peripheral nerve injuries made through the observations on a large scale during the World War. It is also a unique opportunity to demonstrate the need for close cooperation of the electrotherapist, the neurosurgeon and the orthopedic surgeon. The therapeutic conclusions of this paper are based on the following seventy-five cases observed and treated during the past three years at the physiotherapy department of the Reconstruction Hospital.

Nerve lesions.—Brachial plexus, division 1; laceration 1; compression 2; contusion 3; toxic degeneration 1. Circumflex nerve, compression 1; contusion 2. Musculospiral nerve, division 2; compression 2; contusion 3; toxic degeneration 2. Musculospiral and ulnar nerves, compression 1. Mulculospiral and median nerve, contusion 1. Ulnar and median nerves, compression 2; toxic degeneration 1. Ulnar nerve, division 1; laceration 1; compression 1. Median nerve, laceration 1. Sciatic nerve, division 1; laceration 1; contusion 1; toxic degeneration 2. Common peroneal nerve, division 1; compression 3; contusion 1. Deep peroneal nerve, division 1; compression 3; contusion 1; toxic degeneration 1. Facial nerve, infected degeneration 2.

Paralysis after poliomyelitis.—Monoplegia of lower extremities, 13; diplegia of both lower extremities, 4; paraplegia, 11.

Following traumatic or toxic injury to a peripheral nerve the following changes occur: 1. The nerve itself undergoes degeneration (distal from the seat of the injury) or minor disturbances of function. 2. The muscles supplied by the nerve become weakened or fully paralyzed and suffer from lack of nutrition due to the separation from their trophic centre, and due to lack of exercise and they also suffer from overstretching by their strong antagonists if allowed to remain in faulty position. 3. The other soft parts, joints, bones, tendons, suffer from lack of nutrition and develop adhesions, faulty positions, trophic ulcers, and other conditions. Our therapeutic efforts are directed to remedy these changes directly or indirectly.

TREATMENT OF INJURY TO THE NERVE

The injury to the nerve itself has to be remedied by surgical interference, nerve suture or nerve liberation as soon as the surgeon has decided that there is complete or partial division or continued compres-

*Read before the New York Electrotherapeutic Society December 3, 1924, at the New York Academy of Medicine.

sion. Regeneration is effected by the descent of new axis cylinders from the intact central end at a rate of one to two millimetres a day. The deep conversive heat produced by diathermy seems to us to be the most rational physical measure in indirectly assisting the regeneration of the nerve by its nutritional and absorptive effects. According to Langley (1), the atrophy of muscles and later the fibrosed state is due to the fibrillation which always follows severance of the nerve, and on this basis deKraft (2) was the first to advocate diathermy as its effects are sedative and it arrests muscle fibrillation. Diathermy also meets the indication for warming up the parts preceding the muscle treatment. For these reasons we have employed diathermy as the first step in treatment of all of our cases of nerve injury where there was real paralysis present, with extended atrophy of muscles. If a whole extremity was affected, as in case of a brachial plexus injury, diathermy was applied with one moulded electrode just above the shoulder and with the hand in a water bath. In other cases the cuff method or other methods of longitudinal warming up were used. Prolonged heating up to thirty minutes at moderate milliampere reading is preferable to short applications at high metre reading.

Tinel (3) and a number of English and French authors state that the simple passage of a galvanic current seems to be able to stimulate regeneration of a nerve. We feel that diathermy for the reasons given surpasses the unquestionable electrolytic and nutritional influence of the straight galvanic current. We use galvanism only in cases of scar tissue about a nerve for its solvent effect on scar tissue.

TREATMENT OF INJURY TO THE MUSCLE

A muscle deprived of its trophic nerve centre, and untreated, will rapidly undergo atrophy and gradually lose most of its functions. The aim of skillful physical therapy is to preserve as much as possible the function of the muscle so that when the normal nerve conduction and trophic action returns it will not find a useless degenerated mass of fibrous or fatty tissue.

The properties of a normal muscle are (4): 1. irritability, its ability to respond to a stimulus; 2, contractility, its ability to shorten itself in response to a stimulus, usually the impulse of the intact motor nerve; 3, extensibility, the power of lengthening without tearing; 4, elasticity, the ability to regain its normal state after having been extended. Every normal muscle is slightly stretched between its origin and insertion and this tends to maintain the tone of the muscle. In paralysis of a muscle or a group of muscles, the antagonists tend to overstretch the affected muscles constantly and thus deprive them of their elasticity. The first indication in the maintenance of the condition in paralyzed muscles is therefore an orthopedic measure, i. e., to assure complete relaxation of all paralyzed muscles and prevent the shortening of their antagonists. This is accomplished by proper splinting. These splints must be worn until the recovering muscles have attained sufficient tone to exclude their overstretching by their antagonists. The fear of overstretching on the other hand should not prolong splinting unduly as prolonged immobilization in itself will cause periarticular joint changes and muscle atrophy. Early careful passive movements should be instituted through cooperation of the orthopedic surgeon and physiotherapist.

The maintenance of the contractility, irritability and the proper state of nutrition of paralyzed muscles is by far the greatest problem of the electrotherapist. Souttar and Twining (5) in their recent work state, "were we limited to one method of treatment and had nothing but the muscle to consider, we should ourselves prefer electrical stimulation to all other methods of maintaining nutrition in the muscles." The main function of every striated muscle is to contract in response to voluntary impulse. Muscle innervated by an injured nerve, according to Tilney (6), does not contract voluntarily or reflexly and being unable to perform its natural function of contraction tends to revert to noncontractile connective tissue type. By electrical stimulation we can cause movements similar to the normal ones and thus preserve the functional properties of the muscle until the normal impulse returns to carry on the work. According to Burke (7) contractions of any sort, preferably short contractions, exert massage effects and help to prevent fibrous formation within the degenerated muscle. If the muscle is not fully paralyzed (does not show complete reaction of degeneration) but is only weak, the causing of contractions not only prevents the atrophy of the paralyzed muscle bundles, but also exercises and strengthens the nonparalyzed part of the muscle and thus enables it to do compensatory work for the weakened part.

ELECTRICAL STIMULATION WITHOUT CONTRACTIONS

While most electrotherapists and neurosurgeons fully accept this line of reasoning and are satisfied with the clinical results achieved by eliciting muscle contractions, there are in the recent literature statements to the effect that beneficial effects can be achieved by electrical stimulation without causing muscle contractions. Turrell (8) for instance, who previously strongly advocated currents causing contractions, doubts, in his recent textbook, whether a really efficient contraction can be excited in muscle whose nerve has been completely severed as the resulting contraction is confined to a few fibres and occurring in single isolated shocks can have but little influence on tissue drainage. He advises the use of the surging sinusoidal current to the strength necessary to excite faint contractions in the neighboring muscles. Dr. Edward C. Titus has recently recommended that paralyzed extremities be treated with the slow galvanic sinusoidal at a strength which will just cause mild contraction of the face muscles of the patient without regard to whether a contraction of the paralyzed muscles is elicited or not. Cumberbatch (9) also states that there is abundant clinical evidence that paralyzed muscles showing the reaction of degeneration can be successfully treated by a current which causes no contraction or rather no shortening.

The rationale of electrical stimulation of muscles without contraction is based on its influence on another physiological property of the muscle which has been disregarded by most investigators, i. e., its action on the excitability of the muscles. One of the basic laws of electrophysiology is that a constant (galvanic) current produces around the cathode an area of increased irritability of the nerve and muscle

(Pflüger's electrotonus) and subsequently there is response to smaller amounts of faradism and galvanism. If the passage of the stimulating current is repeated regularly the temporary increase of irritability becomes permanent, according to Kowarschik (10). Experiments in physiology prove that every impulse causes some change in the molecular structure of a cell, especially in a nerve cell, and this enables the cell to respond more promptly if the same stimulus acts again. The nerve cell has the property, therefore, to preserve the irritability. Repeated stimulation by a rhythmically interrupted galvanic current will not cause at first any contraction in a bundle of unstriped muscles but continuing these interruptions for a while the muscle will finally begin to contract. The summation of the preceding stimuli has resulted in a stimulus which exceeds the threshold of excitation. Animal experiments have proved without exception that paralysis caused by cutting symmetrical nerve trunks will disappear quicker on the extremity treated by electricity than on the nontreated one.

The enumerated basic experiments of the influence of systematic electrical stimulation on nerve and muscle irritability explain why favorable results can be obtained even without causing muscle contractions. It remains to be decided by observation in large numbers of parallel cases whether better clinical results are obtained by using a technic causing contractions or not. In either case, both experimentally and clinically it has been found that rhythmically varying currents are more effective in the stimulation of paralyzed muscles and nerves than continuously flowing currents. Whichever procedure is used, part of the favorable result in hastening recovery is undoubtedly due to the general nutritional effects of the electrical stimulation preceded by the warming up of all structures. Langley (11) states: "It would be better to produce the accessory results of contraction, that is the nutritive improvement, without the contraction itself."

PRODUCTION OF NUTRITIVE IMPROVEMENT

In our clinical work we utilized the principle of producing nutritive improvement without contractions in muscles which have lost all electrical response and also in cases in severe stage of paralysis. By using weak sinusoidal currents persistently we found that the wasted muscles gradually started to fill out and electrical response first to interrupted galvanism, later to sinusoidal, returned in numerous instances. In cases of severe paralysis or immediately after nerve suture we were very careful not to fatigue the weak muscles by strong interrupted galvanism. Diathermy or radiant light followed by gentlest massage was given for nutritive improvement and followed by weak sinusoidal current, beginning with two to three rhythmic applications over each muscle. The great majority of our cases, however, were past the acute stage and were muscles with partial or full reaction of degeneration, i. e., loss or diminution of faradic response and sluggish or slightly diminished galvanic response. We found that in these cases exercise would be of decided benefit to the muscles and our clinical results were satisfactory. We always used the current which elicited response in the gentlest way in the individual case.

IMPORTANCE OF PRELIMINARY MUSCLE AND NERVE TEST

The first step in planning and ordering electrical treatment in any case of paralysis is a careful and accurate muscle and nerve test, the technic of which is described in a previous paper (12). All muscles of the affected part are tested by faradism and with the condenser set or interrupted galvanism and the comparison with the muscles of the healthy side is charted. If there is response to faradism it is our method of choice for the treatment, as the faradic coil imparts impulses nearest to the impulse of normal nerve stimulation. Experiments of Debadet (9) have also proved that rhythmically varied faradic current caused more than twice the growth in muscles than galvanism.

USE OF FARADISM

In applying faradism we are using either the Bristow coil or the high tension faradic coil. The Bristow coil gives a low voltage faradic, relatively painless current and its strength can be varied very nicely by sliding the iron core in or out of the primary coil. In the high tension faradic coil of Wappler's make, the tension of the current and thus its penetrating or stimulating quality can be regulated by selecting different wire lengths of the secondary spiral; at the same time the current can be made surging and thus much more pleasant and effective by putting it through the sinusoidal part. The technic in each case is to apply an indifferent electrode over the site of the injury—in poliomyelitis over the spine and a small active electrode (an inch to an inch and a half in diameter) over the individual muscles causing six to ten contractions of each. Treatment is usually given three times a week.

To exercise weak but not paralyzed muscles, we have been using recently with satisfaction the clonophore, an instrument delivering a rhythmically interrupted faradic type of current as described for the first time by Dr. Edward C. Titus (13). The contractions caused by this instrument are much more vigorous, yet painless, and at a slow rhythm the muscle exercising action is greater than by the simple faradic current.

USE OF SLOW SINUSOIDAL CURRENT

In muscles lacking faradic response as they do in all cases of real paralysis, the slow (galvanic) sinusoidal is the current of choice. It produces a stimulus of long duration and slowly surging quality to which the paralyzed muscles respond very gently and painlessly. We are always using the method of monopolar muscular stimulation, i. e., a large indifferent electrode over the cervical or lumbar spine or at any place central of the lesion, and a small active electrode over the individual muscles. In all these cases the normal motor point is displaced distally (towards the tendon) and to save time in subsequent treatments it is advisable to mark with indelible pencil the most effective point of stimulation for each muscle. According to the response each muscle is made to contract half a dozen to a dozen times. It is most important that the extremity treated should be warmed preceding and fully relaxed during the treatment. In rare instances, and then mainly for testing purposes, we have used the bipolar method

of electrical stimulation—two small active electrodes over an individual muscle, thus allowing great concentration of current.

SINUSOIDAL VS. INTERRUPTED GALVANIC

The use of the interrupted galvanic current for the eliciting of contractions gave rise to considerable controversy in the past. As long as we believe that it is beneficial to cause contractions in degenerated muscles, interrupted galvanism will supply a need in cases which do not respond to sinusoidal. The difference of action is based on the physics of the two currents and the stage of degeneration of the muscles. In order to elicit a response in a muscle by means of an electrical current, this current must reach a certain intensity and in addition, must last for a certain period before any contraction will occur. In paralyzed muscles a stimulus of longer duration and greater intensity is required. The gradually increasing stimulus of the slow sinusoidal is often not sufficient in advanced degeneration of muscles to cause contraction: it does not last long enough at a certain voltage. Hand interruption prolongs the duration of current flow up to one tenth of a second (the average normal muscle responds to a stimulus lasting one one thousandth of a second; the paralyzed muscle to a stimulus of one one hundredth of a second and more) and at the same time the current strength can be easily increased to the limit necessary. This explains why interrupted galvanism with its longer flow and higher voltage causes response in cases where sinusoidal does not. We use interrupted galvanism with the same technic as sinusoidal, the active electrode being attached to the negative pole of the machine. It is interesting to note in many cases that at first it is necessary to use a larger amount of current to cause contractions, and after the first one or two contractions we can elicit response with markedly less current. One can aptly express it by stating that the muscle needs waking up at first and then responds more briskly. We will also find in a goodly number of cases that after a few treatments with interrupted galvanism response can be elicited by the slow sinusoidal galvanic current. In such cases, naturally, the method of treatment is changed to sinusoidal.

As systematic electrical stimulation, along with other adjuvant treatment is continued, we find that the atrophy gradually disappears and the muscle response improves. Testing by the condenser set every four to six weeks enables us to chart this progress in figures. Finally a time comes when there is the first indication of return of voluntary motion in one or more of the paralyzed muscles. This is proof that the nerve trunk and the motor end plate have regenerated. Response to faradism returns about this time or as a rule somewhat later and a warning has to be given not to replace galvanism too quickly by the faradic current. A muscle just recovering is sensitive towards the more exhausting exercise with faradism and it can be easily tired out so that it will take several days to elicit faradic response again.

USE OF OTHER PHYSICAL MEASURES

While electrical stimulation is our main therapeutic standby in improving the condition of paralyzed muscles, other agents of physical therapy are of considerable importance.

Radiant light and heat is invariably used as an introductory treatment in all cases to promote local nutrition, improve skin conductivity and muscular response by its warming action. It is applied for at least fifteen minutes at a distance of comfortable toleration. In cases of scar lesions combined with peripheral nerve injuries, on account of the disturbed sensation and lack of normal collateral circulation, unpleasant and slowly healing burns easily develop. In such cases, therefore, at least one and a half of the ordinary distance should be used. In cases of cold, clammy, tender extremities we found the whirlpool bath an efficient adjunct preceding electrotherapy used at a temperature of 100 to 110° from one half to one hour. Under the combined action of heat and gentle massage the injured limb becomes warm, red and painless, ready for further treatment.

Massage as an adjunct can be used to advantage although there is modern experimental evidence to prove that it is only of slight benefit in preventing atrophy of paralyzed muscles (14). In paralysis, according to Mennell (15), only the slightest form of massage is indicated because, owing to the atrophy of the paralyzed muscle, pressure may be transmitted to the bloodvessels, causing paralytic dilatation; thus, heavy massage will defeat the end sought. We use massage advantageously for the further improvement of local circulation and for the mechanical elimination of waste products, and ten to twenty minutes' time for a massage treatment is all that is indicated.

Manipulation, active exercise, reeducational movements form an important part in the latter stage of our physical therapy, especially after the response of muscles is beginning to return. A skilled worker will be able to lead the patient to produce contractions by voluntary impulse instead of by an electrical one. All exercises are to be taken after preliminary preparation by heat and electrical stimulation. It has to be remembered, however, that there is a real risk of giving a patient too much physiotherapy and this holds true especially in poliomyelitis cases in which only the gentlest of electrical stimulation and short massage treatments are advisable at first.

The indications for the treatment of the third set of changes in peripheral nerve injury—the changes in the other soft parts, and joints, bones and tendons—are as a rule fully taken care of by the systematic use of the combined methods of physiotherapy as enumerated.

OBSERVATIONS IN INFANTILE PARALYSIS

From a histopathological point of view the changes in a peripheral nerve following direct injury are the same as following poliomyelitis. There is true degeneration of all nerve fibres the trophic centres of which in the anterior horn have been put out of commission. For this reason the treatment of the two conditions is identical, and we followed the same clinical routine in both types of lesions. We have, however, a few important observations to relate in regard to poliomyelitis. The first one is that no case of poliomyelitis is too old for instituting physiotherapy. It takes a long time for the regeneration

of muscles to become complete after the original attack and therefore much can be accomplished even at a later stage in aiding the regenerative process in muscles. Another interesting experience is the sudden improvement in some old poliomyelitis patients soon after proper treatment has been instituted. Turrell (8) says in this respect "it is almost as though there were some latent recovery lurking in the muscle needing only the electrical stimulus to reveal its presence." The third experience is that long, persistent treatment is the keynote of success in these cases, skillfully utilizing all therapeutic measures and avoiding fatigue at any one time. It was satisfactory to record good results after treatment extending over one to two years.

RESULTS

Our results in paralysis following nerve lesions were full recovery in all cases of early nerve suture and in all promptly treated minor nerve injuries. Not so satisfactory end results were achieved in cases which came to us after long standing and which originally had not been recognized as nerve injuries. In these cases the secondary muscle degeneration, the contracture of the antagonists and the joint ankylosis had already caused too much damage for the most skillful supportive and physical therapy. Persistent treatment, however, was able to achieve considerable functional improvement in most of these cases.

CONCLUSIONS

1. For the best interest of the patient a close cooperation of the electrotherapist, the orthopedic surgeon and the neurosurgeon are imperative in every case of paralysis following peripheral nerve lesions or poliomyelitis. The earlier proper physical measures are instituted, the more satisfactory will be the results.

2. Electrical currents simulating the natural physiological impulse are the most valuable single agents in maintaining and restoring the power in paralyzed muscles. Rhythmically varying currents of low tension are the most effective.

3. No electrical modality should be instituted in any case without a preliminary accurate electrical muscle and nerve test.

4. Adjuvant measures of physical therapy may be instituted according to the stage of paralysis.

5. Definite technic and persistency in the measures instituted will bring acceptable results even in late and neglected cases.

The Tonsil and the X Ray

M. V. LEOF, M.D.
Philadelphia

Although my subject is the x ray and the tonsil, I crave your indulgence to bear with me for a few minutes on the scientific basis of electrotherapy or physiotherapy and x ray therapy can in my opinion be included in physiotherapy. Electrotherapy is a science and will do much for medicine, if the medical world will give it a fair trial.

Charles F. Stokes, former surgeon general of the United States Navy, said: "In coining the term electroionization, I have striven to emphasize the point of using in treatment, radiations of suitable wave length, and the dose so small as to affect the groupings of electrons in the atomic structure of pathological cells only, cells that have lost, or have parted with sufficient electrons to disturb their equilibrium. Such cells, groups of cells and organs, in a state of health, should be able to maintain an electronic equilibrium, except as it may be varied in response to excitations and transmissions within normal ranges.

"To electronize a tissue, the electronizing dose should be so minute, that it will not seriously disturb normal tissue cells and yet be sufficient to equilibrate or rejuvenate of course with obvious limitations, abnormal organs.

"Pathological tissue has been shown to be positive in charge, probably by reason of disturbances in the outer shells of its atomic structure, whereby negative electrons have been parted with, they in turn accomplishing less stable groupings. If this biophysical picture is true, then we, by electronizing such a field, may accomplish selective electronization, if the pathological tissues take on, in the outer shells of their atomic structure, sufficient negative electrons, knocked from unstable groupings, to enable them to resume or approach their former equilibrated condition."

Crile, who is as renowned a scientist as a surgeon, and has studied biophysics and biochemistry, says: "Every organic cell consists of two distinct parts—a nucleus and a cell body. The nucleus and the cytoplasm of the cell body require different stains, the nucleus being acid and the cytoplasm being basic or alkaline."

The cell is bounded by a lipoid membrane, a little surface film lipoid material, and the boundary of the nucleus also is a thin lipoid membrane. These membranes are selectively semipermeable, that is to say, each permits certain ions to enter and pass out of the cell or the nucleus. The mass of cell as a whole is made of colloidal material. If the selective semipermeable membrane is destroyed, the cell as a functioning unit is destroyed. If one destroys the membrane, the cell dies, that is to say, the membranes are absolutely essential to the life and function of the cell, and the cells in turn are essential to the life and function of the animal or man. Whenever the physical change, either in the nucleus or in the cell body, has progressed to such a degree that they no longer stain differentially, the cell cannot do its work—it is dead.

"In order that the cell may function and live, why

*Read before the Medical League of Philadelphia, February 23, 1925.

is it necessary that the nucleus shall remain acid and the cell body alkaline, and that the thin intervening membrane shall remain semipermeable? Because—and now I come to theory alone—the cell is postulated to be an electrochemical mechanism. Its life and function are dependent on the maintenance of difference in electric potential between the nucleus and the cell body. In accordance with this conception, the discharge of a cell is like the discharge of battery—the cell, like the battery, becomes exhausted. Life itself is dependent on the maintenance of this difference in potential, or as the physiologist would say, the maintenance of acid alkali balance in the body; but when physiologists speak of acid alkali balance of the body they really refer to the acid alkali balance between the cell body and the nucleus."

So you see that Crile holds the cell, the very basis of life, to be an electrochemical mechanism—an electric battery.

Some years ago, at one of the meetings of this society, Dr. Edeken reported that x ray is used with success in tonsillitis. When I heard that, I felt that the x ray men must be medical hogs; they want to usurp the medical field all to themselves. But one or two years passed and I began to try it. Meeting with success I was relating my experience to Dr. Charles Mazer with whom I was sharing my office.

Said Dr. Mazer, "Two years later, you will forget all about it." Three years passed since, and not only didn't I forget about it, but I am greatly enthusiastic about its value and am hear to remind you, nay more than remind, but plead with you, to give the matter serious consideration.

Histologically the tonsil shows a similar structure to that of the lymphoid glands, with the exception that it is covered on one side by mucous membrane with crypts dipping down from the surface. These crypts have been described as natural test tubes for the growth of bacteria.

Patients that are subject to recurrent attacks of tonsillitis and pharyngitis are continually bathing their pharyngeal tissues in pus coming down from the infected crypts and sinuses. The infection in these cases often involves not only the tonsils and adenoids, but extends to the lymph structures on the lateral and posterior walls, and infratonsillar nodule, lingual tonsil and the cervical glands of the neck.

What is the effect of x ray on these tissues?

1. In proper doses and technic they will remove almost all the lymphoid tissue.

2. They asepticize or sterilize the whole field of penetration. That it will do the first; that is, remove the lymphoid tissue, need not be again said.

It is practically an established fact, that lymphoid tissue is highly susceptible to the rays. That it will do the latter, that is, sterilize the penetration field, I will quote a few instances to substantiate my contention: x ray today is the standard treatment by all dermatologists for acne, furunculosis, carbuncle and other infections of the skin.

Hickney, of Ann Arbor, and Kahn, of Detroit, have been able to clear the throat of diphtheria carriers in from two to four days, administering a fractional dose of x ray in eighty per cent. of the cases so treated.

Schrader, of Berlin, reports results in erysipelas with only one sixth of a skin unit dose.

Kemp, of Leipzig, reports the healings under the rays of a circumscribed peritoneal suppurative process originating from an appendix or following an abortion.

Van Ree, of Amsterdam, Holland, reports 470 cases of glandular lesions of the neck and axilla and groin, a clinical cure in eighty-five per cent. of cases in a few months. Improvement was realized in every instance. I can quote many instances.

If then x ray treatment can and does accomplish these things, that is, destroy the lymphoid tissue in the tonsils, not injuring the other tissues, and also sterilizing the whole field of penetration, the fair question would naturally follow, why not adopt it as a rational method for the cure of chronic tonsillitis and pharyngitis instead of the knife?

What advantages, if any, does this method offer over the knife? Operative treatment involves: 1, Hospitalization; 2, anesthesia with possible risk of pneumonia, lung abscess, hemorrhage. At best, pain, loss of weight, loss of time, loss of tonsils with scarification, a tissue injury and rarely, fortunately very rarely, loss of patient. While x ray treatment involves none of these risks, with hardly any loss of time, the pathological tissues are removed not only of the tonsils but in the whole field of operation, and yet, the tonsils are not lost to the patient.

Now some of my nose and throat specialist friends may object, and say that this method does not cure all cases. Correct, but does asphenamine cure all cases of syphillis? Does antitoxin cure all cases of diphtheria? Is there any one here who will dare deny these remedies in cases where they are indicated? But, say the nose and throat men, why not operate?

Let us compare results. Dr. Witherbee, of New York, who perfected the technic and who probably has done more work in this line than any one else in America, reports eighty per cent. cures in cases observed from one to three years in which the patients suffered from recurrent attacks of tonsillitis and pharyngitis. When I recently met him he told me that he has records of between two thousand and three thousand cases that gave the same results. Other authorities corroborate these findings.

My own experience includes thirty-six cases, too small a number to tabulate and draw conclusions from, but enough to base an intelligent opinion upon. Some of these patients I rayed about three years ago, others two and one year since. In about eighty per cent. the tonsils have been dissolved, nearly all have been markedly reduced in size, while in only two cases was an operation necessary. Nearly all the patients that I have rayed and succeeded in following up, report that they are no longer subject to attacks of pharyngitis, tonsillitis, or laryngitis.

I use Witherbee's technic, the factors of which are—seven inches spark gap, five mil, ten inches distance, time four minutes, three mil aluminum, eight to ten treatments at intervals of two weeks.

On the other hand what are the results of operative treatment? I shall quote from a paper by Dr. Laura A. Lane, Minnesota: "The tonsil question is still one of the most discussed in medicine. Too little attention has been paid to the after results of tonsilectomy and too many operations are done without securing permanent results."

A report from Johns Hopkins Hospital based upon one thousand patients examined before operation and from one to four years after operation, is illuminating: fifty-eight per cent. showed mouth breathing after operation; fifty-five per cent. showed evidences of tissue left after operation; forty per cent. of patients operated upon were still subject to sore throat, angina often being more diffuse.

Tonsillectomy is rarely of benefit in deforming arthritis, never in acute chorea, rarely in acute rheumatic fever, endocarditis and chronic kidney lesions. It is not I who says that, it is a report from Johns Hopkins Hospital.

The same author further says in his paper that during the year ending September, 1922, he had under treatment and followup fifty-two patients treated with röntgen ray, and twenty-four with radium or both combined. The results to date have been very satisfactory. His conclusions drawn from literature and personal experiences are:

CONCLUSIONS

1. A study of more than thirty thousand patients from various sources one to four years after operation shows permanent results in only about half of total number.

2. The tonsil has a function and greater care should be taken to preserve this, especially in childhood.

3. Greater care is necessary in studying patients with diseased tonsils and in selecting patients for operation.

4. Röntgen ray and radium offer a safe method of treatment in carefully selected cases.

5. Results in children and adults have been most striking in cases of decided lymphoid hyperplasia type; also in patients with cervical adenitis associated with tonsil pathology.

6. Longer study is needed to prove permanent disappearance of all symptoms accompanying tonsil and adenoid disease, and some further investigation on the types of tonsils best suited to this form of therapy is also needed.

During my twenty-six years of practice, while I was not a therapeutic nihilist, yet I never felt sure of my remedies with the exception of a few well known drugs. You may consider it presumptuous on my part, but I can't help feeling that in x ray, diathermy, quartz light and some of the other electrical modalities, we have today medical tools of precision. One who is skilled in electrotherapy is as much assured of his position as the surgeon. Given a certain pathological condition, he will know exactly what to do and what to expect.

But two elements are essential: correct diagnosis and proper technic with proper modalities. Let no man buy a diathermy machine or any other physical appliance and set himself up as a physiotherapist for he is doomed to failure. One needs all the modern modalities and one must study the machines and the technic.

X rays will remove tonsils of the hyperplastic type almost as sure as the knife without its risks; will cure ninety-six per cent. of acne cases; a large percentage of adenopathies; a large percentage of the cases of exophthalmic goitre; nearly all cases of fistulæ, and will absorb many fibroid tumors.

Diathermy will benefit and often cure many inflammatory conditions and diseases. Quartz light is useful and highly beneficial in anemias and debilitated conditions, superficial ulcers and various skin diseases. It is a great constructive agent, an excellent adjunct to the other electrical modalities, and is a specific in rickets.

You may consider me too enthusiastic, too empirical or even not scientific, but I can't refrain from stating that radiant heat in conjunction with quartz light and occasional ionization doses of x ray will benefit many cases of duodenal and gastric ulcer.

The riddle of the universe is motion. The key to this riddle is the electron. When we know the laws of the electron, there will be less mystery in regard to disease.

The Hepatic and Cardiac Syndrome*

WILLIAM MARTIN, M.D.

Atlantic City, N. J.

Success in any line of endeavor is largely the result of close application to certain principles and details. In the practice of medicine success depends upon a proper diagnosis, following which correct treatment is possible. For this purpose we must make a careful survey of the patient from many viewpoints, a careful and painstaking history being one of the features, as well as a study of the various symptoms, both subjective and objective. Following with a physical examination and such laboratory studies as are essential, we will have a fair chance of instituting a line of therapy that best judgment suggests. Many of us in the past have failed to carry on in the careful manner just outlined, and particularly in those cases that appear, upon the surface, to be light, or at least lacking in danger.

The cases to be outlined come within this category at one period of their existence, which makes it all the more important for us to consider them at a stage when amenable to therapy, as well as later when they become a menace to life.

We all frequently see the socalled bilious attacks, and no doubt most of us have passed them by lightly with a prescription for calomel or some other cholagogue, and some reference to diet. With recurrent attacks we give such cases some further thought, particularly when the victim suffers from a severe sick headache, yet, even so, we do not appre-

*Read before the American Electrotherapeutic Association, New York, September 11, 1924.

ciate what the pathological process is, or we would be more active both in advice and therapy. For this reason, and with the view of emphasizing the importance of proper care, I present this paper. That these repeated bilious attacks are fundamentally serious can be proved, and I hope to be able to establish their significance as a factor in producing a state of chronic ill health unless relieved or prevented.

First, it will be proper to study briefly the subject from its anatomical and physiological sides. We recognize the location of the liver, that it reposes below the diaphragm in the right side of the abdomen, reaching down with its lower border just flush with the rib line. We also know that it is a blood organ, containing normally one quarter of the blood of the body. Its circulatory system may be thus given in brief: The portal vein, which drains the blood from the alimentary canal, breaks up into branches, which lie at the periphery of the lobules forming the interlobular veins and their branches or capillaries, passing inward between the columns of cells to join the intralobular vein at the centre of the lobule. These in turn empty into the hepatic veins and inferior vena cava. For oxygenation of the working liver cells the hepatic artery supplies the arterial blood. This artery arises from the celiac branch of the aorta. The arterial supply practically follows the venous in its ramifications of the lobules and cells, and the capillaries complete the circuit by free communication with those derived from the portal system. Lying, as this organ does, at the gate of entrance of blood from the alimentary tract into the general circulation, it is influenced materially by the digestive process, at which times the liver becomes overfilled with blood. Normally this congestion is purely physiological and transient. It becomes pathological only after repeated digressions from proper dietary and other regulations, which in time produce a prolonged and persistent circulatory stasis, and irritation of the hepatic cells. So long as these irritating factors remain, so much more marked becomes the stasis, and it is during this progressive stage that the socalled bilious attacks increase in frequency and severity. Right here, were the condition properly recognized, suitable therapy would prove most efficacious and would prevent the disastrous sequel of this syndrome.

If we study the physiology of the organ, we will more completely recognize the important part it plays in the human economy. We will also appreciate its wonderful ability to function in spite of the repeated abuses to which we subject it. No other organ will stand for such treatment.

Not only does the liver secrete bile and store up the glycogen of the body, two important functions, but it also acts as a great chemical laboratory, receiving for action all the products of digestion directly from the alimentary tract, breaking them down and converting them into other substances according to the needs of the body. It seems to have been proved that "the liver is the chief seat of the conversion of ammonia salts into urea, and that it is responsible for the breakdown of the products of protein digestion which are not directly required for replacing tissue waste. The aminoacids normally produced by a protein digestion are absorbed without further change in the blood stream. The major portion of the protein is taken up by the liver, where it under goes deamination, the nitrogen moiety being rapidl converted into urea and excreted by the kidney while the nonnitrogen moiety is carried to the work ing tissues, to which it serves as a ready and im mediate source of energy." (1)

For establishing and sustaining metabolic equi librium, the liver functions must be kept active. An divergence from this normal, whether from extrinsi or intrinsic causes, must be corrected if we can hop to maintain a state of health.

The liver so far has received most of our atten tion in the discussion of the syndrome, but it is no alone involved. We have practically every abdomina organ, the local circulation, and the heart and aorta each and all playing their part in the condition There is a progressive circulatory stasis, the live being the first organ to become affected, as has bee explained. The splanchnics and inferior vena cav appear next in order, and naturally all the organ which receive and discharge their blood supply suf fer from the stasis. As the pressure from engorge ments becomes increased, we will find the right heart next involved, and finally, owing to the *vis a tergo* and *vis a fronte,* the left heart suffers in turn and with it we have a slowly dilating aorta. Th damming off of the venous return from the legs an feet causes their swelling, one symptom that some times suggests Bright's disease, which after being disproved by numerous uranalyses, still causes doub in one's mind until it is thought out from the view point of mechanical obstruction. The same applie to the serous diarrhea so often noted in these cases it is due to the obstruction from mechanical pres sure of the liver, and the diarrhea is purely the resul of nature's effort for relief.

This line of thought—theory, if you care to call i such—is the result of experience with a large numbe of such cases, and is entirely at variance with th accepted statements found in the various writing and textbooks. Proof of the correctness of my con clusions is shown by results of treatment in som instances, and in others by examination of patient made at different intervals, by which progress of th symptoms was noted when treatments were no given. If you will look into this matter, you wil usually find the statement made that cases of cardia dilatation and some other heart conditions are fol lowed by hepatic engorgement. By a citation o cases I hope to prove that the latter sequence is in correct.

When the process in slow, which fortunately i most frequently is, the cardiac involvement is a gradual one, thus saving the patient from any grea amount of dyspnea except under stress. This short ness of breath is Nature's safeguard and offers a warning to the patient that he must seek medical aid There are not a few of the other type of cases usually in robust and stout persons, in whom th myocardium is under too much stress from over eating or some other fault, and a slight overexertion or a severe attack of indigestion with great flatulence will cause a sudden dilatation and death. A case in point is the following:

Case I.—B. C., a business man, aged fifty-five tall and stout, came to me for an examination and opinion with the expectation of placing himself under

eatment a month or so later when business would ow him time for it. His symptoms were typical of is syndrome, moderate hypertension with a high astolic, dyspnea under ordinary exertion, a ndency to attacks or indigestion, flatulence, oderate insomnia, extrasystoles, toxic headaches, d the various minor symptoms usually found. Exnination by palpation and percussion showed a er extending to the pelvic brim, slightly tender on pressure. Colonic flatulence was marked, so e examination was difficult. The heart was normal to murmurs, but there was myocardial insuffiency, as shown by the sounds and pulse. The right art was slightly enlarged, but compensation was parently established, and as there were no clear idences of advanced arterial changes, he was alwed to carry out his plans, although warned as to ssible dangers. His family was told candidly of e dangers of procrastination as well as those of erexertion, and cautioned to keep in close touch ith him in his business. This was possible, as his vo sons were associated with him. A few weeks ter, while on his way home from business, he opped dead on the ferryboat to which he had idently hurried, death, no doubt, being the result a sudden cardiac dilatation.

A more recent case, also fatal in its outcome, ustrates further my contention of the primary liver gorgement with secondary cardiac complications.

Case II.—L. R., aged sixty-eight, came to me cently for an examination and treatment. He was retired business man, large in build, of a strong d robust constitution, with a history of having rely been sick. I had known him for a number of ars, having been at one time his family physician. wo years ago he came down for examination and lvice, but could not remain for treatment. At that me his liver was markedly engorged, extending out two inches below the rib border, and was nder to palpation. There was no cardiac enlargeent, and his symptoms were not referable to that gan, being purely digestive in nature. There was oderate hypertension, no kidney involvement so ar as could be determined by uranalysis, indican eing the sole abnormal content. He and his wife ere informed of the result of the examination, and e was advised to seek the proper treatment at or ear home until he could return and stay. His home hysician did not concur in the diagnosis, informg him that there was nothing the matter with his ver.

After some months of unavailing treatment e sought three other physicians in turn, each givg him the same statement that his trouble was rely digestive, although later one of them told im he had " heart trouble" and treated him for at.

His recent visit to me was made with the thought at further advice and treatment might be had, as e was not satisfied with what was being done. Durg the two years' interval between the two visits, his mptoms had become more decidedly cardiac, and the time he came into the office he was markedly yspneic from the exertion of coming up the few eps, the only exertion he had been under. The yspnea was alarming in its severity, and several inutes elapsed before he was able to converse. After a time of resting, he gave his history of the two years' experience and his symptoms.

For some months he had gradually suffered more and more from dyspnea under slight exertion, this having started about a year before, when under stress that seemed unavoidable at the time. Dyspnea had become his cardinal symptom. He suffered from indefinite pains, largely substernal but a times epigastric, never severe, but disturbing. Attacks of indigestion, with marked constipation, were the principal features aside from those already mentioned.

An examination was made with the following results: marked cardiac enlargement, weak myocardium as registered by the sounds, aortic regurgitation, arterial hardening, liver engorgement, as determined by palpation, extending almost to the pelvic brim, the sensation of a doughy feel to finger pressure. The colon was flatulent and sensitive to deep pressure. Uranalysis was negative. Blood pressure, systolic 242, diastolic 112, pulse 130.

X ray findings were as follows: chest, six feet tube distance, showed the greatest heart diameter, seven and a half inches, arch of aorta, two and a half inches in diameter. Haziness at base of lungs, apparently due to hypostatic congestion, but later shown to be due to an effusion. X ray of abdomen showed lower border of liver one inch above iliac crest with patient in prone position. He was informed as to the seriousness of his case, and warned against any undue excitement or exertion, and his wife was candidly told of the immediate danger. A few days later he died in bed while sitting up waiting for a glass of water to be brought to him.

Diagnosis of this syndrome should be easy, if we will bear in mind the more or less constant symptomatology. Attacks of dyspnea with substernal distress or pain offer a clue which is at least suspicious. Migraine is not a constant symptom, therefore not diagnostic, yet in conjunction with the above and some swelling of the feet and legs and negative urinary findings, it may be considered as fair evidence. Constipation alternating with diarrhea may be accounted for by a mechanical obstruction through the hepatic engorgement together with suppression of bile. Irritation of the intestinal glands no doubt has a bearing, as shown by the serous diarrhea, probably due to a temporary hypersecretion. The substernal distress may at times amount to an actual pain, and may be the result of a reflex from the left brachial neuritis. When the pain occurs in the back it may be due to a colonic distention or a probable neuritic involvement of some of the nerves supplying the area. It may also be from diaphragmatic irritation due to upward pressure of a much engorged liver.

Physical examination of the patients should be thorough. The patient's chest and abdomen should be bared, so that inspection may be easy. With the patient prone, normally the abdomen drops a little or considerably below the level of the rib line, but in this type of case one generally finds the abdomen either level with or rounding up above the rib level. In some cases this is much exaggerated and is pathognomonic of a hepatic engorgement, as is not likely to be found except in cases of dropsy or maligancy. In a particularly thin and spare individual one is struck at once by the abdominal prom-

inence and may consider it to be a fair evidence of what will be found. Palpation and percussion will confirm one's suspicions, but for positive evidence for diagnosis I follow up and check up my findings by the aid of an x ray study of both the heart and liver, having measurements made of a uniform type from recognized landmarks.

Prognosis is a matter of the individual case, depending upon the point to which the case has advanced. Early conditions without marked organic changes in the myocardium are usually favorable, but in advanced cases, such as have been cited, one may always look for an unfavorable result, although in some individuals it is surprising how even these respond to the proper treatment. If one finds a fair amount of improvement after two or three weeks of treatment, it may be safe to offer a hope of an ultimate good result, even though it may not mean more than an extension of life under more comfortable circumstances.

TREATMENT

Treatment will vary in individual cases, although we may lay down certain fundamental principles or lines. Recognizing that circulatory stasis is the underlying feature, we must relieve this before we can hope for a betterment. In this diathermy plays the leading rôle. We must apply this in fairly large doses and for considerable periods of time daily, if we hope for immediate effects. Nothing under a half hour, preferably more, should be the rule, and this applies particularly when the patient is stout. Except in cases with considerable hypertension, we usually follow up with the use of the static wave current with a slow long spark, so that contractions will be marked, thereby avoiding the discomfort or pain produced by a collection of gas that usually follows the shorter and quicker spark. The next step is by the use of mechanical vibration. To tone the myocardium we vibrate the interspaces of the seventh cervical and first dorsal vertebræ for one minute to one and a half minutes as judgment dictates. As routine practice the interspaces of the second to eighth dorsals are also vibrated, doing this from above downward and from side to side with moderate pressure.

Many cases require particular attention to the myocardium, particularly those that show marked dilatation of the heart and aorta. These receive diathermy given in the usual careful manner with properly placed electrodes with a moderate amount of current for from fifteen to twenty minutes, using care in starting and shutting off the current. Many cases of the earlier type will respond to relief of the hepatic engorgement, which is shown by a receding of the cardiac and aortic dilatation with the improvement in the liver size. These changes may be noted by fluoroscope or photographs, and I have seen this happen repeatedly without any applications to the heart. For myocardial insufficiency diathermy is usually advisable, and it is now the uniform practice to give this in all cases as a safeguard.

Those cases with marked hypertension usually require in addition a series of autocondensation treatments. This is preferably given in small doses about three or four hundred milliamperes for fifteen to twenty minutes, the patient reclining upon a couch for the purpose with a thick dielectric. This latter treatment may be omitted when conditions improve. Some obese patients with ptoses may require abdominal supports for a time or until relieved by the other measures. These patients usually suffer from intestinal stasis and, when otherwise suitable, the galvanic sinusoidal current may be used for correction of this condition.

We also must not lose sight of all of those measures that we usually command for all metabolic disturbances, such as diet, properly prescribed exercises, rest, sunlight and all else that promotes a betterment of the body, they all play important rôles in the general plan. As diet is of importance we must supervise it carefully and prescribe the correct food stuffs and advise against too great quantities of any kind, as quantity plays an important part. Attacks of "indigestion" seem often to precede a disastrous outcome of this condition. Too much liquid must be advised against also, as has been the rule in all heart conditions. Moderation in all things is a good rule to work with and go by.

Rest at stated intervals must be insisted upon. It is usually prescribed after meals, particularly after the midday meal. This may be for only short periods of time, fifteen minutes often sufficing, but it should be adhered to strictly. There is no objection to other rest periods when possible to arrange for them.

Exercise, while important from all viewpoints, must be carefully prescribed according to individual needs. Walking is about the best form at first, and this should be graduated so that the patient will not become unduly tired. Never allow enough to produce as much as a suggestion of dyspnea.

Patients suffering from this syndrome often are prone to mental depression, and naturally need encouragement, and this will add much to their chances of improvement. A little study of the patient's psychological side will help materially toward a betterment, if the knowledge thus gained is used judiciously. By a study of the case from this as well as other points of view, we gain a better hold upon the patient and more readily secure his faith and cooperation. Optimism upon the part of the physician helps materially and this, together with plenty of patience and perseverance, will often determine the result.

CONCLUSIONS

To sum up, the real object of this paper is to call attention to the fallacy of the statement often made, that hepatic engorgement is the result of cardiac disease. From the studies made by me in a large series of cases, together with the explanations given in this paper, I feel that the reverse is the actual truth, a reversal of the commonly accepted statement, which means that the cardiac dilatation is the result of the hepatic engorgement. These studies have been in part from cases in which it was possible to examine the heart and liver prior to development of symptoms and to follow up subsequently as in the case reported. It is a misfortune that all cases cannot be seen early, thereby saving much suffering. The subject is a most important one, and I trust that it will incite to more study of these cases in the future by all who are interested, and thus help to establish my contentions.

TRYPARSAMIDE IN NEUROSYPHILIS*

HERMAN P. HYDER, M.D.
Washington, D. C.

(*Continued from page 477*)

CASE X.—This patient was seen by me in consultation late in the summer of 1923. He was badly deteriorated at that time and it had been necessary for him to give up a good position that he had held for several years. His relatives were advised to have him hospitalized. However, they were reluctant and he was not committed here until late in the year. This is a deteriorated type of general paresis. November 21, 1923, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	14
Gold sol.	5555544400.

He was given eight treatments of tryparsamide at weekly intervals, alternating with nine intermuscular injections of salicylate of mercury. On April 9, 1924, his serology showed:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	12
Gold sol.	5554432000.

This patient was again placed on treatment, tryparsamide alone. After he had received six injections his treatments were discontinued on account of his weakened condition. He died shortly after the treatments were stopped.

This was a case in which the patient was so much deteriorated, both mentally and physically, that you would hardly expect any kind of response to any kind of treatment, and he was placed on tryparsamide only, at the request of his family physician.

CASE XI.—This patient was thirty-six years of age when admitted to this hospital on February 7, 1924. He showed mental and physical deterioration, ataxic gait, muscular twitching of face and legs. Insight was lacking and his judgment was poor. Diagnosis, general paresis. His serology on February 13, 1924, was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	54
Gold sol.	5555543210.

His first course of treatments consisted of nine intravenous injections of tryparsamide and nine intermuscular injections of mercuric salicylate. His serology on June 18, 1924, resulted as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	10
Gold sol.	5555432100.

He was now given thirteen treatments of tryparsamide and took mercury by inunction, with the following serological results October 10, 1924:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	8
Gold sol.	5555543210.

*This paper was read before the American Congress on Internal Medicine, March 9 to 14, 1925, at Washington, D. C.

While this patient's serology showed but little change other than the decrease in the number of cells, he has shown a great response from a clinical standpoint.

CASE XII.—Diagnosis, general paresis. This patient was thirty-six years old when admitted here. He gave a history of chancre in 1920, with a short period intervening before the onset of paresis. He was confused and deteriorated mentally; physically his condition was fair. On October 10, 1924, his blood and spinal fluid showed:

Wassermann, blood	Neg.
Wassermann, spinal fluid	4 plus
Globulin	2 plus
Cells per c.mm.	115
Gold sol.	5543210000.

He was given eight treatments of tryparsamide and nine treatments of mercury. His serology on March 12, 1924, showed as follows:

Wassermann, blood	3 plus
Wassermann, spinal fluid, plus in doubles, 4 plus in quadruples.	
Globulin	Neg.
Cells per c.mm.	5
Gold sol.	Normal curve

He was given ten treatments of tryparsamide without mercury and his serology was again taken December 12, 1924, as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid, Neg in singles and doubles, 2 plus in quadruples.	
Globulin	Neg.
Cells per c.mm.	4
Gold sol.	Normal curve

Here is a patient whose serology improved markedly, while his clinical manifestations did not change so much; however, he did improve mentally.

CASE XIII.—Diagnosis, general paresis. This patient was admitted to this hospital December 15, 1923, aged thirty-six years. He was euphoric and unstable mentally, showing a speech defect with symptoms of a deteriorated type of paresis. On March 12, 1924, his serology was as follows:

Wassermann, blood	3 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	8
Gold sol.	3321000000.

The patient was given eight treatments of tryparsamide and nine treatments of mercury. On September 2, 1924, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	Neg.
Cells per c.mm.	3
Gold sol.	5554321000.

He was again put on treatment. When seven treatments had been given they were discontinued on account of patient's failing condition. He died a short time thereafter.

CASE XIV.—Diagnosis, cerebral syphilis. Admitted March 20, 1923. He was suffering from word aphasia, could speak only a few simple words. He was thirty-one years old and gave a history of chancre 1917. He still showed residue of facial palsy, right side. Physically he was in fair condition. On May 28, 1923, his serology showed as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	80
Gold sol.	3321000000.

He was given ten treatments of tryparsamide intravenously and, at the same time, took mercury by inunction. On September 18, 1924, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm	8
Gold sol.	3321000000.

Now he had another ten treatments of tryparsamide, also mercury by inunction. On January 13, 1925, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	3 plus
Cells per c.mm	6
Gold sol	5554321000.

This patient is in good condition from a clinical viewpoint; his aphasia has improved and he shows but little trace of his old facial lesion.

Case XV.—Diagnosis, general paresis. This patient was admitted in September, 1913, aged thirty-three. He was undernourished and weak physically, being confused, showing loss of memory and depression. On October 31, 1923, before being placed on treatment, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm	12
Gold sol.	5555432100.

He was given eight treatments of tryparsamide and nine injections of mercury. On March 12, 1924, his blood and spinal fluid showed:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	5
Gold sol.	Normal curve

He was again given tryparsamide, receiving fourteen doses, with four injections of salicylate of mercury, alternating with tryparsamide. During the latter part of this course mercury was given by inunction. On December 12, 1924, his serology showed:

Wassermann, blood	2 plus
Wassermann, spinal fluid, Neg. in singles and doubles, 4 plus in quadruples.	
Globulin	4 plus
Cells per c.mm	10
Gold sol.	3344321000.

This patient has improved wonderfully clinically. He has become stabilized and reliable. His general reactions are such as leads one to believe that his mentality is on a par with that existing previous to the onset of his illness.

Case XVI.—Diagnosis, general paresis. He was forty-one years old when admitted to this hospital. He gave a history of chancre, 1903. He was disturbed and excited mentally and poorly nourished physically. On June 18, 1924, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm	15
Gold sol.	5554321000.

He was given ten treatments of tryparsamide and, on September 9, 1924, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid, Neg. in singles, 4 plus in doubles and quadruples.	
Globulin	Neg.
Cells per c.mm	6
Gold sol.	4321000000.

Now he was given eleven treatments of tryparsamide; during the latter five weeks of this course he had five injections of mercury. On January 13, 1925, his serology was taken and showed as follows:

Wassermann, blood	Neg.
Wassermann, spinal fluid	2 plus
Globulin	Neg.
Cells per c.mm.	5
Gold sol.	3321100000.

This patient was rather difficult to manage and showed but little desire to cooperate when treatment was instituted. At present he is in good condition physically, well nourished, and he has made a good mental adjustment, being cooperative and anxious to have his treatments continued.

Case XVII.—Diagnosis, taboparesis. This patient was twenty-nine years old when admitted in March, 1924. He gave a history of chancre, 1919. He was euphoric, expansive and somewhat confused. He complained of muscular pains especially in his lower limbs. He was fairly well nourished. This patient's whole treatments consisted of twenty-one doses of tryparsamide, nine injections of mercury, also mercury by inunction. Before treatment was begun on April 3, 1924, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	39
Gold sol.	5555432100.

On June 18, 1924:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	10
Gold sol.	5555432100.

On August 23, 1924:

Wassermann, blood	plus
Wassermann, spinal fluid	4 plus
Globulin	2 plus
Cells per c.mm.	7
Gold sol.	5544321000.

On December 13, 1924:

Wassermann, blood	Neg.
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	11
Gold sol.	5554421000.

This patient appeared to improve rapidly for a time, then his condition became stationary. Taken as a whole there was considerable improvement clinically.

Case XVIII.—Diagnosis, taboparesis. This patient does not give any history of infection. He states he did not know he had syphilis until 1922. He is now thirty-six years old. Mentally he is clear, some euphoria is present. His gait is ataxic. He has spastic condition of the lower limbs, with incoordination marked. On November 21, 1923, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	3 plus
Cells per c.mm.	27
Gold sol.	5555542000.

He was given nine treatments of tryparsamide and ten treatments of mercury. On March 26, 1924, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	2 plus
Cells per c.mm.	10
Gold sol.	5555420000.

He now received eight treatments of tryparsamide and nine treatments of mercury. On July 9, 1924, his serology was again taken:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	2 plus
Cells per c.mm.	6
Gold sol.	5443200000.

(To be concluded)

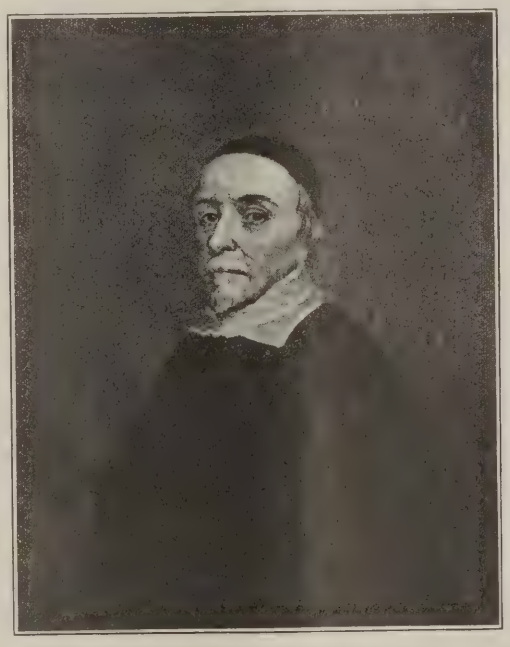
Historical Medicine

Contributions to the Science of Medicine

William Harvey

Scientific discoveries are the result of the researches of various men of keen intellect, sometimes of genius, frequently covering long periods. It is true that William Harvey discovered the circulation of the blood, but a long roll of other workers, preeminent among whom was that supreme anatomist, Vesalius, had paved the way for Harvey's triumph. This does not detract from Harvey's glory for, as just stated, almost all great scientific discoveries have followed a similar course. However, a history of the discovery will be outside the scope of this sketch as well as being superfluous. All medical men are acquainted with the salient points.

The object of this memoir is to present the important phases of Harvey's life, as far as those are known. Aubrey was his historian, but like most of the historians of the time in which Harvey lived, he told the tale in a gossiping manner. Pepys and Evelyn and Defoe, although infinitely better writers than Aubrey, wrote in a somewhat similar, discursive, chatty way, while it is said that Defoe in his history of the plague of London relied more on his imagination than on facts. In order to give as accurate a narration of Harvey's life as possible, the excellent contribution to the *Masters of Medicine Series,* on Harvey, by Sir D'Arcy Power, has been chiefly consulted.



WILLIAM HARVEY

Thomas Harvey, the father of William, was a respectable citizen of Folkestone, which is situated on the coast some sixteen miles from the cathedral city of Canterbury. Indeed, Thomas Harvey was a jurat, or alderman of Folkestone where in 1600 he filled the office of mayor. He was a man of substance and appears to have been a shrewd business man of more than ordinary intelligence and judgment. He was married twice, his first wife dying the year after marriage. William was the eldest of the second family or, as Fuller quaintly expresses it, the eldest of "a week of sons." He was born on April 1, 1578. He had six brothers and two sisters. All his brothers but one were city merchants and amassed much money. The most successful was Eliab, and to his watchful care William owed much of his material wealth, for Aubrey says that "William Harvey took no manner of care about his worldly concerns, but his brother, Eliab, who was a very wise and prudent manager, ordered all not only faithfully, but better than he could have done for himself." Eliab had estates in Roehampton in Surrey and at Chigwell in Essex; he also had a large town house. He built the "Harvey Mortuary Chapel with the outer vault below it" in Hempstead Church near Saffron Walden. Here he buried his brother, William, in 1657 and was himself buried in 1661.

Little is known of the early life of William Harvey. In 1588, at the age of ten, he went to the King's School, Canterbury, where he remained for five years. He then entered, as an ordinary student, Caius College, Cambridge, a college which had been refounded thirty-six years before Harvey's entry by Dr. Keys of Norwich and which was then as now regarded as the college for those who intended to study medicine. In 1597 Harvey graduated as Bachelor of Arts of Cambridge. At this time the great North Italian Universities of Bologna, Padua, Pisa and Pavia were the Meccas for those who desired to study mathematics, law or medicine. Harvey chose Padua which was specially renowned for its anatomical school, rendered famous by the investigations and discoveries of Vesalius and by the work of his successor, Fabricius. Perhaps another reason why Harvey made choice of Padua was, because on account of the tolerance with which Protestant students were treated, a large number of its medical and law students were drawn from England and Scotland and other Protestant countries. University education in those days was cosmopolitan and the universities of Paris, Montpellier and Northern Italy attracted students from all countries. Not much is known of Harvey's career at Padua except that he was a close friend of Fabricius, who at that time was engaged in perfecting his knowledge of the valves of the veins. It seems more than likely that much of Harvey's work was a continuation and amplification of that done by Fabricius. Harvey graduated as Doctor of Medicine at Padua in 1602. His diploma, a very eulogistic one, came into the hands of Dr. Osmond Beauvoir, head master of the King's School, Canterbury, by whom it was presented to the College of Physicians of London on September 30, 1766. This diploma is dated April 25, 1602, and confers on Har-

vey the degree of Doctor of Physic, with leave to practise and teach arts and medicine in every land and seat of learning. It further recites that "he had conducted himself so wonderfully well in the examination, and had shown such skill, memory, and learning that he had far surpassed even the great hopes which his examiners had formed of him. They decided, therefore, that he was skilful, expert, and most efficiently qualified both in arts and medicine, and to this they put their hands unanimously, willingly, with complete agreement, and unhesitatingly.

After obtaining his degree at Padua he must have returned to England at once, as he obtained the degree of Doctor of Medicine from the University of Cambridge in the same year. Soon after his return Harvey seems to have taken a house in London and wasted no time in attaching himself to the College of Physicians. He had qualified himself for admittance to the College of Physicians by taking the M.D. of Cambridge—admission to the college was practically confined to graduates in medicine of the English universities—and was admitted a candidate of the College of Physicians on October 5, 1604, in the stone house once Linacre's in Knightrider Street, the candidates being the members or commonalty of the college from whom its Fellows were chosen.

A few weeks after his admission Harvey married a daughter of Dr. Lancelot Browne, who had been physician to Queen Elizabeth and to James I. Nothing is known as to how Harvey passed the first few years of his married life.

He was elected a Fellow of the College of Physicians, June 5, 1607, and almost immediately sought to attach himself to St. Bartholomew's Hospital. On October 14, 1609, he was elected physician to St. Bartholomew's Hospital. In 1615 William Harvey was appointed Lumleian lecturer. The Lumleian Lecture, founded by Lord Lumley and Dr. Caldwell in 1582, was a surgery lecture established at the cost of forty pounds a year. The manuscript notes of Harvey's first course of lectures are now in the British Museum. In those days the lectures were given with great ceremony. His first Lumleian lecture was delivered on Tuesday, April 16, 1616, and on the following Tuesday Shakespeare died at Stratford-on-Avon.

Harvey continued his Lumleian Lectures year by year, but nothing more is known of them until 1627 when he delivered a series of lectures upon the anatomy and physiology of the human body, more especially of the arm and leg, with a description of the veins, arteries and nerves of these parts.

In 1618, he was appointed Physician Extraordinary to James I, and in 1631 Charles I appointed him Physician in Ordinary and remained his friend through life. Among his patients was the great Lord Chancellor, always a weak and ailing man, and somewhat of a hypochondriac. Curious to relate there was a lack of sympathy between these two distinguished men. In fact, Harvey evinced a contempt for Bacon's philosophy.

Harvey early attained high office in the College of Physicians. In 1629 he received the commands of the King to accompany the Duke of Lennox who was sent to travel abroad. He was nearly fifty-two years old at the time. In 1632 he was again in England and there is no doubt that at this time and throughout his life Harvey practised every branch of his profession. While it is evident that in the first place he was a physician, that he was a surgeon, too, is shown by the fact that in his will be bequeathed to Dr. Scarborough "his silver instruments of surgery." In 1636 he accompanied Lord Arundel, a friend, who was sent to Vienna as Ambassador Extraordinary to the Emperor Ferdinand. He used the opportunity to make the acquaintance of the leading scientific men in Germany. Then came the civil war and Harvey accompanied Charles in his campaign and was actually under fire at the battle of Edgehill where he probably had his first opportunity of treating gunshot wounds. On October 29, 1642, Charles entered Oxford and of course Harvey with him.

During the next year or two Harvey lived quietly at Oxford making dissections and carrying on professional work among the courtiers who thronged the city. The surrender of Oxford in 1645 marks the period of Harvey's severance from the Court and of his practical retirement from public life. He was now sixty-eight, a martyr to gout. Childless, and suffering from heavy bereavements. The bond of friendship which had always marked members of the Harvey family was now exhibited in a striking manner. The eldest brother who had lost his lares and penates at Whitehall and Oxford was a welcome guest for the rest of his life in the houses of his younger brothers. He stayed chiefly at the town house of his brother Eliab or sometimes at his country houses. Occasionally Harvey spent a part of his time with his brother Daniel in the suburban village of Lambeth.

Some curious and amusing details of his habits at this time have been handed down. For example, Aubrey says, "He was much and often troubled with the gout and his way of cure was thus: He would sit with his leg bare, though it were a frost on the leads of Cockaine House, put it into a pail of water until he was almost dead with cold, then betake himself to his stove, and so 'twas gone. He had other harmless little eccentricities, such as walking in the fields in the morning combing his hair. Sitting down exactly at the time he had appointed for dinner whether the company was come or not. That his salt cellar was always filled with sugar which he used to eat instead of salt. He was also very contemplative and was wont to frequent the leads of Cockaine House, which belonged to his brother Eliab, having his several stations in regard to the sun and wind for the indulgence of his fancy; whilst at the house at Combe in Surrey he had caves made in the ground in which he delighted in the summer time to meditate."

Harvey possessed great charm of personality. Beloved by his family and honored by all, the old man went to his grave amid the genuine grief of all who knew him. He died at Roehampton in the house of his brother Eliab on June 3, 1657. It would appear from the account given by Aubrey that Harvey died of a cerebral hemorrhage from vessels long injured by gout and situated rather at the base or internal parts of the brain than in the frontal lobes. Most probably the left Sylvian artery gave way, leading at first to a slight extravasation of blood, which

rapidly increased in quantity until it overwhelmed the brain.

The body was brought to London, where it seems to have been placed in Cockaine House. Here it rested many days, because though Harvey died on June 3d, it was not until June 25th that the Fellows of the College of Physicians received a notice requesting them clothed in their gowns to attend the funeral on the following day. In the meantime Eliab as his brother's executor had determined that Harvey should be buried at Hempstead in Essex, where Eliab had erected in 1655 "the Harvey Chapel" on the north side of the church and also built an outer vault beneath it as a place of sepulchre for his family. The funeral procession started from London June 26, 1657, and was followed far beyond the city walls by a large number of the Fellows of the College of Physicians, many of whom must afterwards have hurried back to Westminster Hall, where on the same day Cromwell, with the greatest ceremony and with all the pomp of circumstance was inaugurated Lord Protector for the second time and invested with kingly power. Harvey was laid in the outer chapel between the bodies of two nieces who were the only occupants of the vault, and like them he was "lapt in lead," coffinless, while upon his breast was placed in great letters his name, his title, the date of his death and his age. On St. Luke's day, 1883, the leaden case containing Harvey's remains was carried reverently from the vault by eight Fellows of the College of Physicians and immediately deposited in a marble sarcophagus built for the purpose in the Harvey Chapel of Hempstead Church, in the presence of the president, the office bearers, and many Fellows of the Royal College of Physicians.

At the age of eighty-seven years the appearance of Harvey is thus described: "A man of lowest stature, roundfaced, with a complexion like the wainscot; his eyes small, round, very black and full of spirit; his hair as black as a raven and curling; rapid in his utterance, choleric, given to gesture, and used when in discourse with anyone, to play unconsciously with the handle of the small dagger he wore by his side."

Unfortunately, the records of many years of careful work done by Harvey were destroyed or scattered by the violence of the times in which he lived. But his liber aureus *Exercitatio anatomica de motu cordis et sanguinis in animalibus* has been providentially preserved. It may be said that this book was issued from the press of William Fitzier of Frankfort in the year 1621 and contains the matured account of the circulation of the blood. Harvey also wrote a treatise on development which is extant and which shows the range of Harvey's mind filled with the knowledge of ancient philosophy, but animated by the experimental spirit of modern science. Harvey may be classed among the discoverers who were creative geniuses. He possessed the boundless inquisitiveness of the discoverer but relied on facts and distrusted imagination. He was averse to theories and pinned his faith to what he could see with his own eyes and comprehended by his own intelligence. Harvey was a cultured and polished man, resembling in this respect his great predecessor Vesalius.

He was a contrast, in many essentials, to his much younger contemporary Thomas Sydenham. One was a devoted royalist while the other was a determined Cromwell man. Harvey was a creative genius while Sydenham was the very embodiment of commonsense. Harvey, although he practised in all branches of medicine, was fundamentally an investigator and was engrossed in experimental science. Sydenham was a practitioner of medicine and helped to revolutionize treatment. Both Harvey and Sydenham had true vision and the initiative to found the principles of approach and to do what they set out to do. Harvey's was the higher form of genius and he takes rank with the very great ones of the earth. Sydenham triumphed through character and laid the foundation of clinical medicine.

Under the Stuarts and the Protectorate of Oliver Cromwell there lived in England some of the shining lights of the medical profession, namely, Harvey, Wiseman, Locke and Sydenham, and that extraordinary genius Boyle the chemist. Indeed the Elizabethan and Stuart periods were prolific of gifted men, among whom Harvey takes his place as one of the brightest ornaments of the medical profession of any age.

Whether Harvey encountered the proverbial fate of pioneers and prophets is uncertain. According to Dr. Munk he had lived to see his great discovery of the circulation of the blood universally accepted as a canon in most of the medical schools of Europe and he is said by Hobbes to have been "the only one that conquered envy in his lifetime and saw his new doctrine everywhere established." On the other hand, in the *Life of William Harvey,* by R. B. Hervey Wyatt, published recently, it is stated that Harvey's contemporaries and fellow practitioners refused to be convinced of the truth it had been his life work to demonstrate. The news of his wonderful discovery fell on deaf ears. It may have been the case of a prophet having no honor in his own country, as it seems certain that the learned scientific men in Europe accepted his views concerning the circulation without reserve. It must be borne in mind that in England at the time scientific medicine was at a low ebb and that there were but few of its medical men who would be able to appreciate intelligently the significance of Harvey's discovery. As a rule their anatomical knowledge was on a level with or considerably below that of Aristotle or Galen while their methods of treatment were almost wholly empirical and fell far below those of the Greek school.

It seems to be very probable that Harvey's discovery was recognized at its true worth by the learned professors of medicine of the European schools, and by a very few in England, but of its opponents there was none who had sufficient knowledge to combat it on really scientific grounds. There are not many revolutionary discoveries which are universally acclaimed at once, for the reason that it needs the acid test of time to establish them. Harvey seems to have been more fortunate in this respect than the majority of prophets and pioneers. Harvey laid the foundation of modern medicine by the discovery of the circulation of the blood and Sydenham at about the same time laid the foundation of sound treatment. Both builded better than they knew.

Editorial Articles

THE EFFECTIVENESS OF RADIUM

Radium seems to be growing in favor as a curative and remedial agent. A drawback to its use has been always the scarcity of the substance, but this handicap has been removed to some extent by the bottling of radium in large quantities which permits of its administration on a far more extended scale than formerly. Recently Mr. Hayward Pinch, the medical superintendent of the Radium Institute in London, assisted by Dr. Moltram, the director of the pathological laboratory and Mr. W. L. S. Alton, the director of the chemicophysical laboratory, have given to the world in a volume entitled *A Clinical Index of Radium Therapy,* a summary of the results of fourteen years' effort in this institute.

In that period 14,500 patients have been dealt with, and 103,000 treatments with radium given. The book discusses the treatment of a large number of diseases and demonstrates how wide is the use of radium in therapeutics. The most important part of the book, however, is that devoted to a consideration of the value of radium in the control of cancer. Naturally enthusiastic statements in this direction are tabooed and it is said that while symptoms are often relieved and life prolonged in cases of malignant disease, it would be extremely unwise to predict that any or all of them would remain free from recurrence indefinitely.

It is further pointed out that the repute of radium has suffered severely from the irrational enthusiasm and unthinking expectation which so often attend the appearance of a new remedy. None the less it is impossible to deny that radium is a therapeutic agent of great, and in some respects of unique, power. The hope is expressed that with increased knowledge and improved technic the time will come when the word "cure" may be used deliberately and justifiably with regard to the radium treatment of a constantly increasing number of cases of malignant disease.

It is not suggested as yet that radium should be the treatment of choice in operable cancer cases. On the other hand, when operation has become impossible, its use is entirely justified. For example, in cases of cancer of the lip "great benefit is very often obtained in inoperable cases, the progress of the disease being arrested, ulceration healed, and hemorrhage and discharge abolished." It is stated that in one form of epithelioma of the cheek, the method of burying tubes of radium in the diseased area will almost invariably bring about the complete disappearance of the lesion, which rarely, if ever, recurs.

Cancer of the tongue which used to be the *bête noire* of the radiologist is now, with improved technic and increasing clinical experience, giving more encouraging results. Internal cancers present exceedingly difficult problems, the greatest, perhaps, of which is the necessity for securing proper irradiation of the growth. The action of radium irradiation upon any living cell, if used long enough and of the requisite degree of intensity, is first, increase of activity, then arrest of activity, and finally degeneration and destruction. Normal cells and pathological cells, however, behave differently when under the action of radium. Tumor cells are stimulated more easily, their vitality is inhibited more quickly and degeneration occurs more rapidly.

Therefore the problem before the radiologist is mainly one of dose and of period of irradiation. Successful radium treatment means that the dose must be as accurate as possible and the exposure extending over a sufficient length of time to destroy the pathological cells without appreciably affecting the functions and vitality of the normal ones, thus enabling repair to be accomplished satisfactorily. An insufficient dose may possibly act as a stimulus causing increased growth, while an overdose may destroy healthy cells.

Growing cells are most amenable to treatment by radium and in consequence certain quick growing tumors respond more rapidly to treatment than those which grow more slowly. Experience has taught that it is wisest to give a maximum dose at the first exposure to radium. If further treatment is required, subsequent doses must be smaller. As the sensitiveness of various types of tumor cells to radium differs widely it is possible to make a rough classification on this basis. The radiologist by reason of accumulated knowledge is now able to work with a considerable amount of scientific precision. He knows, to some extent, how the various tissues of the body may be expected to react to the different radium rays, and has quite a clear idea of the variations of reaction of abnormal and normal tissue. This knowledge is essential and only those who possess it should attempt to use radium for therapeutic purposes.

The science of radiology, while out of its swaddling clothes, has hardly reached adolescence and is still somewhat in the experimental stages in spite of the fact that some of its achievements have been signal triumphs and that its future is full of promise. In the use of radium, as in the use of any therapeutic agent whatever, the personal equation must be studied and taken into consideration. Individuals of

a highly neurotic temperament are more susceptible to the effects of radium than those of a phlegmatic type. Persons who exhibit a high degree of susceptibility to the violet rays of the sun are liable to a darkening of the skin some months after treatment with radium.

The book of Hayward Pinch and his colleagues is a stimulating account of pioneer work in radium and of the progress made during fourteen years. Knowledge is not accurate or precise, but advance is being made steadily in that direction and the outlook is encouraging. The value of the book chiefly consists in the fact that it is a restrained record of work done scientifically and conscientiously.

SPRING MEDICINE

Most of our hygiene and more of our medicine is still in the realm of speculation. The following, if admittedly speculative, suggestions may not miss the mark more than much which is set down with more assumption of positive authority. Most of science is the result of putting two and two (often very small twos) together, and possibly the comparison of some very large figures may be worth while.

The common diseases—the diseases which affect everybody or nearly everybody (and which being so near at home we hardly consider diseases when compared with Addison's, acromegaly or other rare and big named ones)—are carious teeth and constipation. Nearly a hundred per cent. of us suffer from the former, and at least half as many have found our way with them to the tinkerer of bad teeth—the dentist—nearly a hundred per cent. of us are bothered by the latter at some time and to some extent, and half of us find our way to the opener of bowels—the physician. Let us stand far enough away and consider, and we must all admit that these are the outstanding abnormal conditions of civilized man. They may not kill but they curse us continually. They are, however, both symptoms. The cause is known beyond cavil; in both cases the wrong quantity and quality of food, or bad nutrition. The wild animal has neither the one nor the other of these disorders, nor has he them in captivity if he has wise keepers.

But let us go deeper. If the materials for teeth are bad, will not other tissues receive bad stuff for their making and upkeep. We know that more than mere bone is affected in rickets and may not constipation also bring about effects on tissues? There is evidence which the assertions of recent experimenters do not refute, that it does. We know that colonic bacteria must flourish under the circumstances and that defenses against these, locally and generally, must be much overworked at the time. There is a tendency to discredit Metchnikoff's theory of premature old age, but was there not more truth in it than even Metchnikoff dreamed? It may do little good to remove the great bowel, but it may make all the difference in the world what and how much it contains, especially in the superfed.

Focal infection now holds the centre of the stage, and we are blaming teeth, tonsils, sinuses, appendices—all the nooks and crannies where bacteria may congregate—but neither teeth, tonsils nor any other such structure is directly and primarily to blame for their focal infection. Putting two and two together, isn't the blood, by which means alone such focal infection can occur or be kept alive, at fault, and, back of the blood, its source—the food?

The evidence from the spring medicine habit fits in here, for "spring medicines" (through their gentle action on the colon) really clean the blood, for the time, from stuff accumulated, the results of a left-over, too vigorous, cold weather appetite. Our ancestors knew a few things in practice, if not in theory, and even bleeding may not have been a bad thing in a day when they ate much more for pleasure than we do.

How can a tissue—dental, tonsillar, or other—resist disease when it is not supplied with the right materials or is deluged daily with wrong materials? And why should not cells go insane on the subject of reproduction and become cancerous under such circumstances? There is more proof for such a theory than for any other that has been advanced.

STATE MEDICINE?

There is a feeling amounting almost to apprehension among certain groups engaged in the curative branch of medicine that the sanitary profession is invading the province of the practitioner and in so doing is inflicting damage upon the pocketbooks of those engaged in the remediation of disease. It is barely possible that this may be true in certain isolated instances, but the general tendency of the public health movement is to be an aid to the practitioner. To be sure, it is the aim of preventive medicine to reduce, and, so far as is possible, to prevent disease. It is realized that it is far better for the community to be maintained in a state of health rather than to be cobbled up from time to time. This idea, however, is a long way from accomplishment and while reduction in the preventable communicable diseases has deprived the practitioner of a certain amount of income, this has more than been compensated for by the increase in physical examinations and in the early recourse to medical service which has been brought about by the public health movement. Similarly, there has been a tremendous increase in the number of operations for the removal of tonsils and adenoids and there are far more early operations for the re-

moval of cancerous growths today than there were ten years ago. Antituberculosis work has stimulated physical examinations and early treatment, and many patients are now consulting the physician who, hitherto, would probably not have gone to him at all. It has also been stated that the sanitarian is changing medicine into state medicine and that one of these days the public will be entitled to medical treatment without fees, just as today it is entitled to education in the public schools without paying tuition. This is not a matter which falls within the province of preventive medicine. There are adequate agencies to see to it that only the qualified practise medicine and so long as the public receives good medical attention, preventive medicine should be, and is, satisfied. If the public is learning to prefer the public clinic to the private practitioner, it is not the fault of the sanitarian. As a matter of fact, is it not the practitioner, who, by giving gratuitous service in free clinics, is rapidly teaching the public to prefer free public medical service and hence is bringing state medicine into being?

GASTROINTESTINAL TROUBLES AND CANCER

A great deal of discussion, some of it somewhat acid in character, has taken and is taking place with regard to the causation of cancer. No one specific cause of malignant tumors has been discovered yet nor does it seem likely that any such discovery will be made in the near future.

One of the best contributions which has been made to the subject recently, is in the form of a paper entitled The Cause or Causes of Cancer, read by Dr. Adam H. Wright, of Toronto, before the meeting of the American Public Health Association held in Detroit on October 22, 1924, and published in the *Medical Press and Circular*, November 5, 1924. This paper is termed one of the best, deliberately and mainly for the reason that it considers a much debated and disputed matter from the viewpoint of common sense. Dealing with the relationship of gastrointestinal disorders, and of chronic intestinal stasis in particular, to cancer, this article is the concentrated essence of common sense. The author does not state boldly that chronic intestinal stasis is a cause of cancer but only suggests that it may be a prominent factor in its causation and explains why he thinks this outcome is possible. In the first place, he points out that cancer is largely, if not essentially, a disease of civilization and is almost unknown among those who lead primitive lives. Of those he quotes in support of this contention is Dr. Hindhede of the Danish Bureau for Nutrition Research in Copenhagen, whose strong views on this aspect of the situation were given by a well known medical writer in the *New Statesman* of September 27, 1924.

Dr. Hindhede is an uncompromising adherent of the belief that cancer is a disease of civilization and supplies potent testimony to this effect. As for Wright's argument that chronic intestinal stasis, one of the evil results of civilization, may be regarded as an important factor in the causation of cancer attention is drawn to the fact that long continued irritation is allowed to be a cause of cancer. Chronic intestinal stasis brings about various conditions of irritation in the intestinal tract. And again it is affirmed that prolonged intestinal stasis, by producing a toxemia which in the course of time invades the whole system, so weakens the defensive powers of the body, that disease, cancer for instance, gains the upper hand. It is almost an aphorism that cancer never affects a healthy organ. There are then two reasons why chronic intestinal stasis may be a cause of the exciting of cancer, because it provides the foci of irritation and the favorable soil.

Dr. Wright professes himself fully conscious of the truth of the statement that our only reliable means of fighting cancer at the present time is early diagnosis and prompt surgical intervention, but he emphasizes the suggestion that by a more careful diet and by more rational methods of living in other ways than is now customary in civilized countries, the occurrence of cancer may be sometimes, perhaps, frequently avoided. He also states another obvious truth that by following these precepts, even if cancer is not largely prevented, several other ailments or diseases arising from or aggravated by long continued intestinal disorders, mainly marked by chronic constipation, will be nipped in the bud.

Wright takes the stand, that as existing methods of treating cancer are inadequate because cancer is seldom diagnosed, often such diagnosis is impossible, at a stage sufficiently early to make surgical measures successful, he therefore agrees with Sir Arbuthnot Lane that methods for prevention shall be given a trial, as, for example, a more suitable diet and a more healthy mode of living in every respect.

There is little doubt that in the discussions on diet which have been edifying the medical profession and the general public of late too great stress has been laid on the importance of the hypothetical vitamines. It has been asserted by more than one, whose opinions carry weight, that much of the innutritious properties of the ordinary man's diet is due to lack of one or other of the vitamines, that is, to vitamine starvation. This view seems to be owing to lack of proportion of outlook. Other constituents of diet, mineral salts, to wit, are of quite equal importance to the vitamine content, indeed, if the

mineral salts are present in their proper quantities, the vitamines may be left to take care of themselves. As Dr. Wright says, the most deadly evil of civilization, as far as diet is concerned, is overeating and drinking. One point, which few writers on cancer touch on, is as to whether a predisposition or susceptibility to cancer can be inherited. Some individuals, the majority of the population it seems, are immune to cancer. Is there a solid substratum of truth in our grandfathers' views that certain diatheses were transmitted to children by parents or ancestors, and may this hold good to some extent for cancer?

The question of cancer being a disease of civilization is certainly worthy of serious consideration, and Dr. Wright deserves the thanks of the medical profession for dealing with a matter of world wide importance with restraint and logical reasoning combined.

REFORM

The Reverend Charles F. Potter has made a great to do about the handling of psychopathological cases by the psychoanalytical methods. He was especially strong in his remarks concerning the uncontrolled nonmedical analysts. Here his point is fairly well grounded but quite overstressed. He cited as the evidence of wreckage the reports of former neurotic patients who asserted that they had been made worse by analytical treatments and had had to pay for them. No doubt Potter meant well. Perhaps it would have been somewhat better had he investigated more thoroughly. But careful investigation does not seem to go hand in hand with the writing of sensational newspaper reports. Potter's broadside appeared in *The World*. The editors of this paper felt he had gone a bit far, and said so in an editorial which appeared shortly after the publication of Potter's article.

Psychoanalytical procedure, in spite of the fierce opposition which it once excited, is now becoming the accepted method of approach to psychopathological problems. It holds a place in the field of mental therapy analogous to that of surgery in general medicine. It is used most extensively in our great government hospital, St. Elizabeth's, in Washington, D. C., and has been found to be the only available method of approach in many state hospitals for mental diseases. Psychotherapists, who once could see no benefit from analysis, now realize that they can make no progress without a working knowledge of this art. No former method has been as efficient in the entire field of functional disorders.

This editorial is not intended as a defense of psychoanalysis. It concerns the newspaper activities of such men as Potter. He tried to be fair, so fair that he leaned over backward when he admitted that he could not stomach the tirades of the extremist opponents of analysis, and he thought there must be some good in analysis in spite of what they said. He left himself the customary loopholes, yet his article as it stood was misleading and, at best, a piece of cheap newspaper notoriety. Had he been more sincere and less noisy he could have been infinitely more effective, had he gone directly to the medical profession and put his case before them. He would have had a hearing and at the same time got more accurate information. As it is, he exposed himself to ridicule and accomplished nothing.

The reputable analysts are recognized medical men, well trained in the general field of medicine. The medical profession has the matter well in hand. The medical profession would not think of entering into the field of theology, no matter how firmly certain of its members believed that certain tenets held by some religious sect might be false or misleading or even harmful. This matter would be left in the hands of the theologians. Potter no doubt has gone back in his concepts to a remote primitive level, to the time when the medicine man of the tribe served the spiritual and physical needs of the community. That was a long time ago.

No, the medical profession respectfully requests Potter and others similarly minded not to interfere unduly in its affairs. If they feel that they must, let them come to the medical profession to learn a few salient facts and then if they have any complaints to make, let them be made to those who are responsible. Otherwise his sincerity will be doubted. The motives that prompted him will be questioned and his perhaps well meant gesture appear absurd.

THE CENSUS BUREAU'S NEW LIFE TABLES

The United States Abridged Life Tables, 1919-1920, prepared by Elbertie Foudray under the direction of Dr. William H. Davis, have recently been issued by the Census Bureau. Some of the data shown in these tables are of especial interest. In expectation at birth, the decade 1910-1920 shows the same general progress as the preceding decade. Females still have a better expectation than males, and the colored show more improvement than the white. They have about the same expectation at birth that the white had thirty or forty years ago. The figures show that, up to extreme old age, white and colored males have made a steady gain in expectancy; in old age the figures cannot be taken as reliable on account of various difficulties in getting and tabulating available data for that age. In the

case of both sexes and colors the decline in expectation in middle life so noticeable in 1910 has disappeared. This improvement in longevity at mature ages is shown consistently in the male populations of all important States and cities from which data for the two periods have been worked up into life tables.

From 1900 to 1910 there was a tendency for the urban mortality rates to fall more rapidly than the rural. The tables show that the greater decline in mortality in cities has continued during the past ten years. Chicago, New York City, Philadelphia, and Boston all show a greater increase in expectancy than any of the five states tabulated. Although urban rates appear to be falling more rapidly than rural, they are still much higher.

The improvement in expectation at each age noted in the case of males is not so evident in the data for females. Except for expectation at birth, only slight progress would appear to have been made in the past decade, if the years 1919-1920 are taken as representative. Some improvement in the expectation of life for white females may be observed after the thirty-year mark, but the tendencies manifested from 1900 to 1910 have not continued. The expectation for colored females has improved slightly since 1910; but, except for childhood, they have failed to recover the ground lost from 1900 to 1910. This means that the traditional advantage held by females over males in longevity has been considerably reduced.

A phenomenon of these tables, which did not show itself in the previous years tabulated, is the excess of mortality among young adult females. There is a wide variation in these mortality rates, from California and Washington, with no excess at all, to Kentucky with an excess at each age from seventeen to fifty-seven years. At the ages of twenty-two, twenty-seven and thirty-two, the period when the excess is most marked, we find that it is greatest in the Central and Lake States. New England and other Eastern States and also the far Western States have but slight tendency for an excess of the female rate over the male at these ages. This phenomenon is reflected in a number of causes of death, based on the age group 20-24. All causes showed a female excess rate of thirty-one per 100,000 in 1920; but in 1910 the male rate was in excess by seventy-four per 100,000. Violent causes and typhoid fever have only an adventitious relation to the phenomenon. In both the male rates are greatly in excess, and in both there has been a marked decline in the last ten years. On the other hand, there has been an increase in a condition limited to females, namely puerperal causes. Tuberculosis and influenza pneumonia are the two other conditions involved in the female mortality excess in the age group twenty to twenty-four. The reasons for this heavy mortality among young adult females are obscure. The tables only indicate the facts.

CONJUGAL TUBERCULOSIS

Dr. Paul Roussel has recently contributed much to our knowledge of the question of tuberculosis contagion between husband and wife, based on exact statistics. According to Roussel, contagion between husband and wife, even among the working classes, is rare, and occurs only after long cohabitation. In the total statistics it is not over 5.2 per cent., and in open cases 11.56 per cent. On the contrary, in the same families, the children are extremely sensitive to tuberculosis infection, and in the total statistics their minimum proportion is 25.02 per cent., and 37.59 per cent. in open tuberculosis of the parents.

Transmission from husband to wife appears to be by far the most frequent, this fact being due to the particular receptivity of women at the time of pregnancy, puerperium, and lactation. When transmission of the disease between husband and wife does take place, it is mild in over sixty-six per cent. of the cases.

The infrequency of conjugal tuberculosis can be explained by the immunity the mild repeated superinfections confer upon the adult in respect to slight contaminations arising in everyday life. Cases of conjugal contagion rarely represent massive contamination; usually there is predisposition to tuberculosis dependent upon heredity. A delayed marriage may be permitted under certain reserves to patients with socalled cured tuberculosis which has been so for several years. In this respect, we should be always more guarded in the case of women than men, and a union between two tuberculous subjects should never be advised. Conjugal prophylaxis consists of sleeping in separate beds, a discipline of coughing and expectoration, and a wise sexual life, a long interval between pregnancies, and the maintenance of good general health in the healthy conjoint.

Dispensary supervision and social prophylaxis favor the good results obtained by individual effort. In the etiology and prophylaxis of tuberculosis, Dr. Roussel rightly points out that there is a real danger when only the bacillus is considered, as well as only considering the question of soil. The truth is to be found in both theories. Calmette's remark: "No matter how fertile may be the soil it will never grow seeds other than those scattered by the laborer, birds, or winds" can be completed by Vallin's remark that "The soil of the forest of Fontainebleau is strewn with acorns, not one of which will probably ever become an oak tree."

News Items.

New Health Bulletin.—The *Ohio Health News*, a semi-monthly bulletin, is being issued by the Ohio State Department of Health.

Leyden University Anniversary.—The University of Leyden, Holland, recently celebrated the three hundred and fiftieth anniversary of its founding.

Memorial to Doctor Bunnell.—The California Medical Association at its annual meeting in May will unveil a bronze memorial commemorating the naming of the Yosemite Valley by Doctor Bunnell, who, in 1851, as a member of the Mariposa Battalion, was one of the first white men to enter the valley.

Florence Nightingale Memorial Service.—Elaborate services, attended by two thousand nurses representing all nursing organizations of the city, will be held May 17th at the Cathedral of St. John the Divine, New York, to commemorate the memory of Florence Nightingale, and also the nurses who died during the war.

Venereal Disease Control.—The board of health of Salt Lake City, cooperating with the state board of health, has put into effect a rule providing examination of all men and women found under circumstances giving rise to a reasonable suspicion they have a venereal disease, quarantine and enforcement of treatment.

New Federal Hospital.—The establishment of a hospital for the eighty thousand government employees in Washington, is being considered. The institution would be built and maintained with small monthly payments from the salaries of the employees, and the Government would be asked to direct the campaign for funds and manage disbursements.

Supervision of Radio Health Talks.—Through the efforts of the special committee on press and publicity of the Medical Society of the County of New York, a number of the more important broadcasting companies in New York City and Newark have consented to voluntary supervision of all talks on health topics going out from their stations. Such talks will be submitted to the society's representatives for approval. The stations which are cooperating are WEAF, WJY and WJZ, WOR and WNYC.

Broad Street Hospital.—The executive committee of Broad Street Hospital, New York, and its acting president, Dr. William H. Dieffenbach, have issued a statement that the assets of the hospital exceed its liabilities by a sum of upwards of one half million dollars, and that its deficit in operation is that of any hospital operation on a charitable basis, a deficit to be made up by donations from the public and friends of the hospital. With a change in financial management, the present financial stringency is being overcome, and the hospital brought back to its former prosperous condition.

Gifts and Bequests.—Mount Sinai Hospital of New York, has received by the will of the late Mrs. Emma Rosenwald, $100,000, and a contingent interest in the estate.

Kingston General Hospital, Toronto, has been bequeathed $300,000 in the will of the late Charles Sandwith Campbell, a Quebec attorney.

The Greenwich (Conn.) Hospital receives $10,000 under the terms of the will of the late Allen B. Forbes.

Personal.—Dr. Philip R. Lehrman, assistant professor of psychiatry at the New York Post Graduate Medical School and Hospital, has been appointed visiting physician to the Manhattan State Hospital, Ward's Island, to take charge of the psychoanalytical department.

Dr. William Seaman Bainbridge of New York, is delegate from the United States to the third *Congres International de Medicine et de Pharmacie Militaires* recently held in Paris. His reports of the first two congresses, held in Brussels and Rome, respectively, have been published in Washington.

Dr. J. O. Polak, of Brooklyn, spoke before the Flatbush Medical Society on The Medical and Surgical Cervix.

Dr. Amos O. Squire, for fifteen years resident physician at Sing Sing Prison, has been endorsed by the executive committee of the Westchester Republican County Committee for the newly created post of county medical examiner.

Dr. Max Thorek of Chicago has been appointed corresponding member of the Surgical Society of Paris, France, and elected a member of the Academy of Medicine of Torino, Italy.

Banquet of Peoples Hospital.—The annual banquet of the Peoples Hospital given by the board of directors and medical staff was held at the Hotel Biltmore on Saturday, April 18, 1925. A bronze tablet was dedicated in honor of Vahdah Anna McCullough.

American Psychopathological Association.—The American Psychopathological Association will meet in Washington, D. C., May 7th. Papers will be presented by Dr. Alfred M. Barrett, Dr. J. Ramsey Hunt, Dr. L. Pierce Clark, Dr. L. E. Emerson, Dr. Harry S. Sullivan, and Dr. Trigant Burrow.

American Psychoanalytic Association.—The American Psychoanalytic Association will meet May 12th, in Richmond, Virginia. Papers will be presented by Dr. I. H. Coriat, Dr. Gregory Stragnell, Dr. K. A. Menninger, Dr. Trigent Burrow, Dr. H. S. Sullivan, Dr. C. P. Oberndorf, and Dr. Adolph Stern.

Association for the Study of Allergy.—This association will hold its annual meeting May 26th, at Atlantic City. Papers will be presented by Dr. Karl K. Koessler, Dr. Allen Eustic, Dr. W. W. Duke, Dr. I. S. Kahn, Dr. Charles A. Spivacke, Dr. William Engleback, Dr. Harry S. Bernton, Dr. G. T. Brown, Dr. Milton B. Cohn, Dr. Ralph O. Clock, Dr. George N. Jack, and Dr. George Piness.

American Association for Study of the Feebleminded.—The forty-ninth annual session of this society will be held in Raleigh, North Carolina, May 8th to 11th. Meetings will be devoted to Delinquency and Crime as Related to Mental Deficiency, Psychology and Mental Deficiency, Relation of Mental Deficiency to the Public, Motivation of Special Class Work, The Institution for the Mentally Deficient, Pathology and Physical Characteristics of Mental Defectives, and Psychiatry and Mental Deficiency.

Women's Medical Association.—The Women's Medical Association of New York City will have an informal dinner at the Women's City Club, Wednesday, May 20th, at 6.30 p. m. All women physicians and students, members and nonmembers, are invited. Applications for reservations enclosing check for two dollars should be made to Ethel D. Brown, M.D., 26 Gramercy Park, New York City, before May 18, 1925. The annual meeting of the association will follow the dinner.

Women's Medical Society of New York State.—This society will hold its nineteenth annual meeting on May 11th, at Syracuse, New York, in connection with the meeting of the state society. A scientific program will be given at the morning and afternoon sessions after the invocation by Dr. Eliza M. Mosher, honorary president, of Brooklyn, and an address of welcome by Dr. Elizabeth I. Shrimpton, of Syracuse, chairman of the committee on arrangements. A banquet will be held following the meeting.

Coming Meetings of Societies.—The American Medical Association will hold its annual meeting May 25th to 29th, at Atlantic City. The House of Delegates will convene at ten o'clock Monday, the 25th, at the Hotel Traymore. The Bureau of Registration will be located on the steel pier, where the scientific exhibits will also be held. Diagnostic clinics will be held in Music Hall, and the scientific sections will meet in the various hotels.

Other organizations announcing meetings in connection with the American Medical Association are: American Association for the Study of Allergy; American Gastroenterological Association; American Laryngological, Rhinological and Otological Society; American Proctological Society; American Therapeutic Society; Association for the Study of Internal Secretions; Medical Library Association; Medical Women's National Association; Radiological Society of North America.

State societies which will meet in the near future are:

Arkansas Medical Society, Little Rock, May 13th to 15th; Connecticut State Medical Society, Bridgeport, May 20th and 21st; Medical Association of Georgia, Atlanta, May 13th to 15th; Illinois State Medical Society, Quincy, May 19th to 21st; Iowa State Medical Society, Des Moines, May 13th to 15th; Kansas Medical Society, Topeka, May 5th to 7th; Maine Medical Association, Bar Harbor, June 23d to 25th; Massachusetts Medical Society, Boston, June 9th and 10th; Mississippi State Medical Association, Biloxi, May 12th to 14th; Missouri State Medical Society, Kansas City, May 5th to 7th; Nebraska State Medical Association, Lincoln, May 12th to 14th; New Hampshire Medical Society, Manchester, May 19th and 20th; Medical Society of New Jersey, Atlantic City, June 18th to 20th; Medical Society of the State of New York, Syracuse, May 12th to 14th; North Dakota State Medical Association, Fargo, May 18th and 19th; Ohio State Medical Association, Columbus, May 5th to 7th; Oklahoma State Medical Association, Tulsa, May 12th to 14th; Rhode Island Medical Society, Providence, June 4th; State Medical Association of Texas, Austin, May 5th to 7th; West Virginia State Medical Society, Bluefield, June 9th to 11th.

Foreign Correspondence.

VIENNA LETTER

(*From our own correspondent*)

Vienna, *March 19, 1925.*

MENTAL EXHAUSTION IN CHILDHOOD

Dr. Strauch, a reputed specialist on children's diseases, gave a lecture before the Vienna Medical Society on the importance of examining and recognizing mental exhaustion in children. He stated that this was the task of the practitioner as well as that of the school doctor. This question was put in the foreground by the unfavorable nutritive conditions during the war and during the after war years, and by the great spread of tuberculosis. Another factor leading to the rapid mental exhaustion of children was the recurrence of nasopharyngeal diseases. Of course, children afflicted with these diseases are backward and show slow progress in their studies. Often they are punished by their parents and even by their teachers by whipping. How much better it would be if the monthly visit of the school doctors would extend also to the examination of the nasopharyngeal apparatus of backward children. In most cases of diagnosed mental examination in children the most noteworthy pathological states were anemia and flaccid muscles. Professor Embden advocates phosphoric acid in such cases in the form of acid phosphate of sodium. This he maintained would increase the physical and mental efficiency in a great measure. Professor Noorden also had corroborated the efficacy of this drug in cases of mental exhaustion. He made extensive experiments with it and tested the physiological effect of the drug. Encouraged by the good results, he suggested the administration of phosphoric acid in any form. The lecturer, Dr. Strauch, had given the drug for experimental purposes to half the children in one class, without selection. He found surprising results in the improvement of these children. However, he did not recommend the drug to be given to healthy children, but insisted on administering it to weakly, emaciated children or convalescents and also to anemic, backward children.

PROFESSOR MELLER

The waves of the Hochenegg affair have scarcely subsided when a fresh storm was aroused by a lecture held by Professor Joseph Meller, the renowned oculist of the Vienna University. Nominally the patients who have been referred to the clinical hospital for admission by Meller, chosen on the outdoor department of the clinic, had been subjected to undue interrogations from the part of the clerks in the admission office as to their ability to pay the hospital expenses. It even happened that patients whom Meller desired to admit to his clinical ward for an instructional purpose were declined by the clerks unless they paid the hospital expenses in advance. In one of his lectures Meller criticized his method before his students and said that they missed many interesting cases on account of the conduct of the admission office. The situation was described in papers but was not remedied, despite the fact that Meller made a complaint against this abuse to the Ministry of Public Welfare. Thereupon Meller gave notice of his resignation and at the same time ceased to continue lecturing, much to the regret of his students. The medical faculty of the university and also the Ministry of Public Instruction have done everything in their power to persuade Meller to change his mind but to no avail. Only when all forums had promised due satisfaction to him did he resume his lectures, at which occasion his students, the professors and lecturers of the university appeared at his lecture and gave him a warm welcome.

DECREASE OF MEDICAL STUDENTS IN GERMANY

Up till now the number of first year medical students formed about one fourth of the total number of students. This proportion has greatly decreased in the latter years. The main reason for this is the excessively high living in Germany, which is at present one of the most expensive countries of Europe, not excepting England. In the winter season of 1923-24 the ratio of first year medical students to the total number of medical students on all courses has been as follows:

	Total number of students	*First year students*
Berlin	1,467	96
Bonn	506	14
Breslau	571	8
Erlangen	239	1
Frankfurt am Main	337	12
Jena	517	38
Köln (Cologne)	168	..
Kiel	402	4
Marburg	353	4
München	1,394	133
Nürnberg	640	76

DEATH OF PROFESSOR BUMM

Ernest Bumm, secret councillor, the director of the gynecological clinic of the University of Berlin, died in his sixty-sixth year in Munich in consequence of an operation performed on his gallbladder. The deceased was born in 1858 in Würzburg, where he attended the secondary school and also the university and was promoted to the degree of Doctor of Medicine in 1880. He was characterized by an iron energy, exact knowledge, great conscientiousness, ardent thirst for science, diligency, and great eloquence, as well as extremely sympathetic individual qualities. It is no wonder that with all such valuable properties he attracted a great number of physicians from all parts of the globe. The German imperial court had given him their confidence. His lecture room was always full. His best known medical work was *Treatise to the Study of Obstetrics,* which appeared in 1902 and since then has had fifteen editions, and has been translated into almost all languages. Dr. Bumm had acquired great fame by his early studies of the x ray treatment of uterine cancer.

GOITRE QUESTION IN BAVARIA

The Bavarian government has asked Professor Pfaundler and Professor Wiskott to make a special study on the occurrence of goitre in Bavaria. The government was induced to do this on account of the fact that the Bavarian health resorts which attracted countless visitors from abroad in former years have been missing the full pocketed foreigners in recent years. Some lay journals tried to explain the absence of foreign visitors by the alleged frequent occurrence of goitre in Bavaria in the afterwar years.

This statement has not been borne out by facts, because even the farthest southern parts of Bavaria, which border Switzerland, are practically free from goitre, although it is undeniable that goitre is a popular disease in Switzerland. The question blanks sent to all practising physicians of Bavaria confirm the fact that there is no trace of goitre. The figures do not attain the figure of the number of goitre cases in Switzerland. It is, at any rate, undeniable that there are parts in Bavaria which are rich in struma cases; this holds particularly true to low lying, densely populated rural places. In general, the disease is more common in females than in males. Internal secretory disturbances have been observed in conjunction with struma rarely, and even then they were only cases with manifestation of hyperthyroidism. On the basis of this report the government did not feel inclined to introduce systematic mass prophylaxis and special magistrative interference.

A QUESTION OF COMPETENCY DECIDED BY LAW

There was a railway accident in 1923 near Oradea Mare, Rumania, caused by the proved negligence of a switchman; among the severely injured was a girl of twenty, a bride, whose wedding ought to have taken place sixteen days after the accident, and who sustained compound fractures on both legs. She was taken to the hospital in Oradea Mare, where she was treated for about four months and afterwards she was taken to Vienna, to the hospital of Professor Spitzy, for some plastic operations. Despite the precise treatment she is able to walk with crutches only and wears orthopedic boots. She has spent one thousand two hundred and fifty dollars for medical attendance since the time of the accident. She claimed 3,000,000 lei compensation from the State Railways partly to cover her expenses, and partly to compensate her for losing the prospect of marrying and as compensation for her maintenance for her life, being entirely incapable to carry any breadwinning occupation. She is the daughter of a well to do private official. The State Railways refused to pay this sum, arguing that she ought not to have gone to Vienna for treatment, as the King of Rumania had had an operation for appendicitis a short time ago and the operation was done as well by a Rumanian doctor, Duvara.

Therefore the representative of the State Railways asked the Court to appoint a committee consisting of notable doctors to verify the necessity of having gone to Vienna. Members of this commission were: Dr. Djuvara, of Bucharest, the family doctor of the King of Rumania; Dr. Emil Jacobovici, professor of surgery at the University of Cluj; Dr. Pop Alexandru, surgeon of the Municipal Hospital in Oradea Mare, and Dr. Garö, forensic doctor. The medical committee had asked for eight days to compile its report. They made an x ray to ascertain the present condition of her feet. The counsel for the defense produced sixty original bills, and emphasized the fact that all doctors who have treated Miss Mihályi had sympathy for her on account of her tragic fate and charged modest fees, that had she gone to Bucharest it would have not made any difference from a financial point of view. From the other hand Vienna is half as far from Oradea Mare as Bucharest. The Court did not decide the case.

Letters to the Editor.

LATERAL TRACTION

NEW YORK, *April 3, 1925.*

To the Editor:

I note with interest that Dr. De Bar, in a letter to the MEDICAL JOURNAL and RECORD states that "Maxwell in the early eighties was the first surgeon to use lateral extension together with direct extension" in the treatment of fracture of the neck of the femur, and that Dr. Bradford has employed the same principle in his abduction splint without mentioning Maxwell's priority.

This statement is incorrect in two particulars. Maxwell was not the first surgeon to use lateral traction. He described the treatment in the *Chicago Medical Journal and Examiner,* for May, 1876, giving credit for the method to Dr. G. W. Phillips, of Dixon, Ill., who described it in the *American Journal of the Medical Sciences,* for October, 1869. Therefore, to quote Dr. Ruth, Maxwell's former associate and now the chief exponent of the treatment, "to Dr. Phillips must belong the honor and the credit of first describing and using this method of treatment." —*Albany Medical Journal,* January, 1913.

Aside from the question of priority, which may be of interest to Dr. De Bar, there is no similarity in the mechanical principles of the two methods. Lateral traction if carried to an extreme would actually pull the fragments apart. Abduction if carried to the normal limit would force them into contact by tension on the capsule. In actual practice the combined traction of Phillips, Maxwell and Ruth by supporting the limb and disentangling the overlapped fragments is far more effective than any of the routine methods.

The abduction enforced by Dr. Bradford's splint is not sufficient to assure fixation, and is supplemented by direct traction, which in an ambulatory brace is most uncertain in its action.

Neither method assures the quality of fixation required to provide the opportunity for interstitial repair of a complete fracture of the small part of the neck, and neither method is mechanically adequate to correct resistant deformity, the first essential of functional repair. Both are dependent upon the uncertain and inconstant action of traction and, therefore, on the quality of the nursing. Each is doubtless of service for selected case, the field for the splint being particularly limited for obvious reasons.

The abduction treatment alone is adequate to apply surgical principles in every type of fracture. It places the responsibility for the result therefore in so far as it is determined by the initial opportunity for functional repair on the one who undertakes the treatment. It is because of a lack of standard based primarily on the mechanical inadequacy of the methods in use that explains the past and even present neglect of this the most disabling of all fractures, and it would be unfortunate now that it may be enforced if the statement were accepted that the atrophy necessitated by fixation of the fragments causes nonunion, which might be prevented by the stimulation of such mobility as the abduction splint permits.

ROYAL WHITMAN.

Book Reviews

THERAPEUTICS

Clinical Therapeutics. By Alfred Martinet, M.D. Translated by Louis T. deM. Sajous, M.D. In two Volumes. Philadelphia: F. A. Davis Company, 1925.

The author, on page 14, calls attention to the recognized but often forgotten fact that some of our most learned members of the medical profession fail in the therapeutic management of patients, while many practitioners who are not well grounded in the science of medicine and surgery still, by their devotion and care and careful observation of patients, arrive at therapeutic success. He also says, on page 16, "The art of therapeutics is partly an individual gift which may be developed by practice and endeavor." These references show the trend of the author of these volumes to urge the individualization of the patient who has a disease and to emphasize the fact that, whatever the diagnosis may be, the patient has the right to have his disturbing symptoms prevented or ameliorated. This is emphasized on page 17 where he says that "proper clinical therapeutic management requires a correct and complete diagnosis, accurate knowledge of the therapeutic agencies available, and the adaptation of these measures to the individual patient and his illness."

On pages 21 and 22 the author discusses the importance of drugs as evidenced by their increasing use or greatly decreasing use. The reviewer believes that this method of determining the importance of a drug is more or less fallacious as, like the rest of the civilized world, the physician is subject to fashion. Therefore a drug may be of little importance but greatly in vogue, and many a valuable drug has been forgotten.

The author, in the reviewer's opinion, makes the mistake of trying to describe a lot of useless drugs. Books on materia medica and therapeutics are the only ones that perpetuate antediluvian material. All other books on medical subjects omit the old stuff and add the new, but books on materia medica and therapeutics while describing the new material seem to think that they must also describe the old material. A mistake. Another criticism of this book would be the tendency to copy prescriptions of anywhere from four to eight ingredients because they were pet prescriptions of some noted men. These suggestions for polypharmacy should be eliminated from modern books.

The discussions are very good on special and serum treatments and colloid therapy. The sections on climate, hydrotherapy, medicinal springs, exercise, electricity, and the therapeutic uses of x ray and radium are all excellent. The chapters on physical procedures are well written and clear in their description of these measures.

Volume II dares to have the title of *The Treatment of Symptoms and Diseases.* The reviewer is glad to note that the author dares to make important the treatment of symptoms. A successful clinician cannot ignore uncomfortable symptoms in his management of the patient. The neglect of such treatment is what sends many patients to practitioners of healing (?) who know nothing about the human body.

The section on the treatment of symptoms is arranged alphabetically and represents 263 pages of this volume. The rest of the volume is devoted to treatment of disease, with the exception of a final section on treatment of poisoning.

The translator has done excellent work and has added one or two parts to the book, to its improvement.

These volumes represent an enormous amount of careful work by the author and also by the translator, and they will be a valuable addition to any physician's working library.

The type, indexes, and the publisher's work are excellent.

BACTERIOLOGY

Pathogenic Microorganisms. By William Hallock Park, M. D. Philadelphia and New York: Lea and Febiger, 1924. Pp. 811.

Of all the textbooks on bacteriology of such reasonable compass that they occupy a single volume, the most practical is the *Pathogenic Microorganisms* of Park, Williams, and Krumwiede. In it is reflected the practical spirit of the Public Health Laboratory of the New York City Board of Health, now thirty-two years old, and for so many years under the scientific guidance of the senior author. The medical student, the practitioner, and even the general reader will find admirable and sound information concerning our present knowledge of bacteriology and serology, cemented together with sufficient theory to render it consistent. Certain additions have been necessitated in this latest edition by the rapidly increasing knowledge of certain phases of immunity, such as the bacteriophages, the newer work of the Dicks on scarlet fever, and the extensions of our knowledge concerning toxin-antitoxin immunization in diphtheria, as well as the results of the wide application of the Schick test. The bibliography contains references up to 1924, but the index is not quite up to the standard of the rest of the book.

CRIME IN RELATION TO INSANITY

Crime and Insanity. By W. C. Sullivan, M.D. Medical Superintendent, Broadmoor Criminal Lunatic Asylum. New York: Longmans, Green & Co.; London: Edward Arnold & Co., 1924. Pp. vii, 259.

This book contains much important matter and a point of view that cannot be brought too emphatically before the public. The material of the writing is designed primarily for students of psychiatry but it meets a very real need for information at large as to the incidence of crime in relation to insanity. This is emphasized from both sides through the author's presentation: the crime as so often only one form of the symptomatic manifestations which result from a pathological background, and the proneness of such a diseased mentality to result in those acts which in their effects constitute injury to, therefore crime against, society. Thus crime and the criminal nature are discussed not as separate entities in themselves but as features in a wider situation. As such they can be understood only by investigation of each in-

dividual case in its mental condition. This is by no means to neglect the social aspect of the deed but only so much the better to attack the problem of society's own safety. Various mental diseases, together with mental defects, are set forth in detail with the special incidence of crime in relation to them. The author suggests a distinction between crimes due to economic conditions and those resulting from the impulses which find occasion to break through under conditions of mental disorder. He is not unmindful of a closer relation between these two groups of criminal acts than might at first appear. Yet this is one of the places where the interpretative consideration of impulsive and other criminal acts might have been carried even deeper. The book, however, is very instructive and suggestive in its setting forth of the interrelation of mental disorders, with their psychological and physiological (endicrinous) background, and the outbreak of criminal deeds. It gives thus a broad basis on which to consider the question of responsibility.

LOCAL ANESTHESIA

Local Anesthesia Simplified. By John Jacob Posner, D.D.S., Chief of the Dental Department Harlem Dispensary. With fifty-five illustrations. St. Louis: The C. V. Mosby Company, 1924. Pp. 114.

To the dentist who is seeking a simple and conservative account of the principles and technic of local anesthesia, this book can be heartily recommended. It is brief, direct and well illustrated. The details concerning structure and nerve supply are not obscured by lengthy discussions of anatomy and physiology. The technic is outlined to meet the practising dentists' requirements. Emphasis is laid upon two injections. They are the new supraperiosteal injection for infiltration anesthesia and the mandibular injection for block anesthesia. With these two injections alone it is possible to treat ninety-five per cent. of the cases that arise in ordinary practice.

DISEASES OF NERVOUS SYSTEM

Précis de pathologie interne. Maladies du système nerveux (Cerveau, cervelet, méninges, pédoncules cérébraux, tubercules quadrijumeaux, protubérance, bulbe). Par Le Dr. Henri Claude. Avec 97 figures dans le texte. Bibliothéque du Doctorat en médecine publiée sous la direction de A. Gilbert et L. Fournier. Paris: J. B. Baillière et Fils, 1924.

This volume is replete with details of every phase of disorder manifest in the various portions of the nervous system. Its systematic arrangement, its clear, concise statements, make it a ready book of reference for the student or the practising physician confronted by the simpler or the more complicated nervous disorder. The book is not devoted to therapeutic measures, yet even as it stands it leaves one with the lack of a comprehensive functional point of view. This would have set these disorders, even in their more mechanistic appearance, in a relation to a personality trying to function behind its disabilities, or perhaps, in faulty function, having established certain phases of the disorder. Even a word of emphasis upon this dynamic relation of anatomical lesion and organism would have given a vital significance to these otherwise authoritative but somewhat overstressed details.

MEDICAL GUIDEBOOK

Consultations du Médecin Praticien. Guide de Pratique medico-chirurgicale journalière, par le Dr. Fred Blanchod. Paris: J.-B. Bailliere et Fils, 1925.

The reviewer confesses to a certain prejudice, common to medical minds, against guide books to practice in which one looks up the treatment under disease labels and in which the author skips nimbly, if not like the chamois "from peak to peak," at least from abscess to accouchément and thence to adenitis and aphthæ. It stands to reason and to experience that this method, while convenient and timesaving, is apt to be unscientific as well as uneven. Dr. Johnson said of a female professional whistler that the surprising thing was not that she did it badly but that she did it at all. The surprising thing about Dr. Blanchod's work is not that it is not done badly, but that it is really done very well. For those who need this kind of a book, this is just the kind of book they need.

SCHOOL MEDICINE

An Introduction to School Medicine. By H. Leslie Cronk, M.A., M.D. London: H. K. Lewis & Co., Ltd., 1925.

This practical little volume from the pen of a health officer of experience deals with the methods of examination, diagnosis, treatment, and prevention "of minor departures from health which a child attending school with more or less regularity may present." It is more a matter of determining whether the child actually is in full health and up to the physiological requirements of its years, than of disease or even prepathological states. Cronk's study includes growth, malnutrition, food requirements, sleep, postural deformities, to each of which a chapter is devoted. There are, in addition, sections on special topics, notably an excellent résumé of the important subject of visual defects in children.

MATERIA MEDICA

A Textbook of Materia Medica for Nurses. By A. L. Muirhead, M. D., and Edith P. Brodie, A.B., R.N. Second edition. St. Louis: C. V. Mosby Co., 1924. Pp. 190.

Miss Brodie is to be congratulated on the splendid revision she has made of Dr. Muirhead's book. This small textbook presents all the information that is needed by nurses on the subject of drugs. The book is terse, well written, well arranged, and should be owned by every nurse. The publishers are to be commended for the good clear type, splendid arrangement and the general fine appearance of the book.

THE ARAB

The Arab at Home. By Paul W. Harrison, M.D. New York: Thomas W. Crowell Company, 1924.

An exceedingly readable account of a medical missionary's adventures in desert Arabia. The writer is indeed a brother to all mankind. His labors for the Arabs have rewarded him richly in friendship, in the tender understanding of suffering humanity which makes the medical profession so immensely worth while. The wonders of modern medicine are indeed open sesame to brotherhood between man and man, primitive tribe and Christian teaching. Especially interesting is Dr. Harrison's understanding revelation of acceptance of theory and rejection of fact by the natives he treated, as related to all the details of missionary work. No proselytizing work in this, but a human account of humane work.

Medicoliterary Notes.

Suit has been brought, according to press reports, against a Berlin theatre where a revue has been running depicting a scene on one of Germany's de luxe steamers in which the passengers are seasick. The company owning the steamer, which is designated by name on the stage, maintain that their business has been affected detrimentally by the seasick scene.

* * *

When G. P. Putnam's Sons published Robert Keable's *Numerous Treasure* they left out of the book a recipe for a cocktail invented by the author and named in honor of his heroine. It was feared that prohibition enforcement agents might object to the publication of information that might make some of us break the law. But who would want to experiment with a cocktail invented by an Englishman?—*N. Y. Times.*

* * *

Dresden, Germany, has devised an interesting and effective method for disseminating public health information and publicity. A calendar has been designed and printed, with pertinent and attractive illustrations, and containing notes, rules and articles on health subjects by German physicians of note. Although the calendar is printed in German, the cartoons and pictures are so much to the point that it may be used to advantage in other countries.

* * *

The annual report of the Surgeon General of the Navy for 1924 has been issued. This report announces the establishment of a new Planning Division of the Bureau of Medicine and Surgery in order that more consideration could be given to the problems of the Medical Department of the Navy "in future war plans."

* * *

England now has her version of *What Price Glory?* in a play entitled, *Tunnel Trench,* by Hubert Griffith, recently produced at the Prince's Theatre, London, by the Repertory Players. In commenting on the realism of the play and its lack of all melodramatic elements, a recent British review says: "The steady drag of the presentation was the perfect vehicle of the dramatist's intention. The modern warrior for whom there is no joy in battle, no triumphal junketings at Rome, no memories that are glad to the mind, plods through this play with the patience that is more terrible than passion. . . . One heard people saying, 'Yes, it may be wonderful, but why should we be harrowed with these reminders?' The answer is in the news of the day."

Among interesting articles in March magazines are: The Insects Are Winning, by William A. Dupuy, in *Harper's;* Biology Holding the Future, by J. B. S. Haldane, in the *Forum;* Harlem, Mecca of the New Negro, by various authors, with illustrations from drawings by Weinold Reis. in the *Survey Graphic;* and Crime and Punishment, by Horace J. Bridges anl Clarence Darrow, in the *American Mercury.*

* * *

Announcement has been made that the first International Congress on Child Welfare will be held at Geneva, August 24-28, 1925. The program will include addresses and discussion on medical, hygienic, sociological, legislative, educational and propagandic problems. A prominent place on the program will be given to the education of the children of all countries in international good will.

Sard Harker, John Masefield's only novel, has been selected by the *London Times* as one of the four best novels published in Great Britain during 1924.

* * *

Mental Hygiene inaugurates its ninth year of publication with a January number of unusual interest. Among the articles included are The Application of Psychiatry to High School Problems, by Anne T. Bingham; A Study of Certain Erotic Practices, part 2 of the report based on the replies of 2,255 women to questionnaires prepared by the Bureau of Social Hygiene; One Hundred and Fifty Policemen; Some Observations Upon Probationary Policemen of the Detroit Police Department, by Jessie M. Ostrander; Drug Addiction in Its Relation to Crime, by Lawrence Kolb, M. D.; Dementia Precox and Crime, by Dorothy Crounse; "Good" Education and "Bad" Children, by Ira S. Wile, M. D.; Report on a Questionnaire Study of Personality Traits with a College Graduate Group, by F. L. Wells, Ph.D.; and A Group of Psychoneurotic Ex-Service Men, by Lloyd H. Ziegler, M.D.

The Department of Physiology of the University of Toronto has recently been making an investigation of the preparation of insulin in large quantities from bony fishes. Conclusions have been submitted by Prof. J. J. MacLeod that in the opinion of the investigators both cod and pollock may be made a profitable source of insulin in the Canadian Maritime Provinces.

Physicians as playwrights have made two appearances on Broadway during this season. The plays for which they are responsible were *In the Near Future,* by Dr. Abraham Goldknopf, produced by the Mutual Theatrical Society, and *The Complex,* a play based on psychoanalysis, by Dr. Louis Bisch.

* * *

A study of the germicidal properties of ultraviolet rays has been made recently by the Bureau of Standards of the U. S. Department of Commerce. A report states that the shortest waves were found to be the most active and forceful, since they are capable when sufficiently intense of causing death through an exposure of only one second. Longer wave lengths required a greater intensity and had a much slower action. Tests showed that the germ killing effect of ordinary sunlight is due to waves so short that they are invisible to the human eye.

* * *

A recent publication which has raised a storm of discussion is J. B. S. Haldane's *Callinicus,* published by Dutton as one of the Today and Tomorrow Series. The book is an argument and plea for the use of gas as the least brutal of all the weapons of modern warfare, for so it is to the author, who is a biochemist at the University of Cambridge. It is brilliantly written and well worth reading, however much the reader may disagree with the writer's conclusions.

The Boston press has recently reprinted some of the answers to questions in a civil service examination which covered some of the aspects of mental hygiene. A few of the answers follow: A moron is a person who has fallen to the lowest ideals possible. A moron is a wise fool. Moron—a species of immortality difficult to define with words or eradicate when found. Moron—an infant whose parents leave it and do not acknowledge parentship. Kleptomaniac—one who steals while walking in his sleep. A child afflicted with mental hygiene is one whose brain is not normal. A child suffering with mental hygiene should be placed in a proper school to cure same as much as possible. One question was, What action would you take in the case of theft of fruit? One of the answers was, Perhaps the child is a kleptomaniac. Remove her from the fruit; or perhaps the parents also steal fruit. Discipline the parents.

The Child and His Problems, by Alice M. Hutchinson, M.D., with a foreword by H. Crichton Miller, is a late publication of Williams & Norgate, London, England. The writer is senior assistant at the Hospital for Sick Children, and at the Tavistock Clinic. There are chapters on the nervous child, the difficult child, and the only child, as well as much material that should be of value to those dealing with socalled normal children.

In the new Hebrew University which opened April 1st on Mount Scopus, Palestine, the various departments are being organized as means are available. At present there is a microbiological institute and a chemical institute, which form the beginning of the faculties of medicine and science; research institutes in physiology, physics and mathematics are being organized. The establishment of these particular institutes at the opening of the university was decided upon because the public health problems of Palestine present numerous questions in bacteriology, serology, immunity and experimental medicine generally.

Abstracts from Current Literature

PHYSIOTHERAPY

Action of Röntgen Rays on Blood Pressure.—Carl chroeder (*Zentralblatt für Gynäkologie,* August 16, 1924) sserts that the fall in the blood pressure of ten to forty illimetres of mercury following the use of röntgen rays, specially in cases of hypertension, may be explained as fol- ows: the resulting erythema dilates the capillaries, which, n turn, leads to the fall of the blood pressure. The dilata- on of the capillaries is apparently the result of the action f the röntgen rays on the vascular nerves.

Treatment of Cancer of the Lip by Irradiation.—ernard F. Schreiner and Louis C. Krebs (*Journal of Can- er Research,* July, 1924) classify their cases into three roups:

Group I included all lesions confined to the lip up to in- olvement of the whole lip, with no demonstrable involve- ent of the lymphatics. Fifty-eight out of sixty-nine of hese patients were clinically well; seventy-eight per cent. ver a period of three years and fifty-two per cent over a eriod of five years.

Group II included lesions of the lip with definite meta- tatic involvement of the lymph channels, but still classified rom the viewpoint of surgery as operable. Thirteen out f thirty-six patients were clinically well: thirty-nine per ent. for three years and thirty per cent. for five years.

Group III included far advanced tumors of the lip with netastases in the neck which were fixed, involving the peri- steum or ulcerating, socalled inoperable cases. In this roup radiation is of little value.

There are two types of tumor on the lip, the papillary or roliferating type and the infiltrating type. These two types hould be clearly distinguished from each other as they espond differently to irradiation, the infiltrating type being omewhat slower to respond to treatment. The proper reatment is to plant bare tubes of radium in the base of the umor. The authors used unfiltered x rays in the treatment of all superficial tumors. The lymph bearing areas were reated by means of high voltage x ray. In the cases of the econd group healing in at least thirty-four per cent. could e brought about by x ray therapy alone.

X Ray Treatment of Whooping Cough.—Henry I. Bowditch, Ralph D. Leonard and Lawrence W. Smith (*American Journal of Diseases of Children,* September, 1924) assert that the younger patients and the earlier cases of whooping cough seem to derive the greatest benefit from x ray therapy. The most striking effects of the treatment have been seen in the reduction of the paroxysms, both actual, in the number of whooping attacks, and relative, in a diminution in the severity of the paroxysms. The same diminution in the number and severity of the paroxysms occurs whether the disease is at the onset of or later in the paroxysmal stage. The blood picture roughly parallels the clinical improvement. No positive cultures of the Bacillus pertussis were obtainable after the third week. Complement deviation experiments show that there is a specific antibody produced during the disease. In the cases complicated by bronchopneumonia, the same relief from the paroxysms was noted following the use of the x ray. This in itself is the chief factor in effecting a cure, for by conserving the strength of the child in this manner his resistance must be considerably heightened. In addition, physiotherapy in the form of diathermy was used in the cases complicated by bronchopneumonia.

Resorption Effect of Diathermy in Gynecological Diseases.—Ivan v. Büben (*Zentralblatt für Gynäkologie,* September 6, 1924) uses three different procedures to obtain the resorption effect by diathermic treatment in gynecological diseases: The first type is the abdominodorsal, in which by means of a small plate electrode placed over the symphysis and a larger one under the back, the entire lesser pelvis is uniformly heated through. With this method the grade of heat attained is not intensive enough and, therefore, this procedure is not used very often.

The vaginal application is used much more frequently, as in this way the uterus and its surroundings can be heated through most intensively. An olive electrode, supplied with a thermometer of suitable size is inserted into the vagina and a plate electrode, the size of the hand, is placed in position over the area complained of either on the abdomen or on the back. With the proper application of the external electrode the diseased area can be treated with any desired size of cone of heat and in this way completely heated through.

Whenever vaginal applications are impossible for some reason or another, the rectal application may be applied. This procedure is indicated, chiefly, in those forms of residual exudate and adnexal diseases that are localized in the region of the culdesac of Douglas, in which the pathological tube or ovary is fixed to the pouch of Douglas and therefore can be influenced by the vaginal electrode only incompletely. In the rectal application, intensive heat may be applied to the changes of fixation in the region of the culde-sac of Douglas with the aid of the olive electrode inserted into the rectum and the plate electrode applied externally.

Even though diathermy is far superior to all the other procedures that produce resorption of exudate, nevertheless it is not a panacea to be used in every case. Like all other methods of treatment it has its contraindications; if these are not observed it may even do harm with the amount of heat that cannot be obtained by other therapy.

Radium Therapy of Carcinoma of the Uterus.—I. Belugin (*Zentralblatt für Gynäkologie,* September 6, 1924) was able to show that with collections of pus localized in the lesser pelvis the use of radium is extremely dangerous, in so far as it may lead to a peritonitis or generalized infection. This develops the more readily the thinner the capsule surrounding the pus focus and the closer to it the radium is applied. The main factor in the development of a generalized infection is apparently to be ascribed to the chemicobiological effect of the radium rays, on account of which the treatment with radium is contraindicated in the presence of pus foci in the lesser pelvis. Inasmuch as irradiation therapy is the only possible method of cure in old and inoperable cases of carcinoma of the uterus, it is advisable to produce an autoimmunizarion of the patient before instituting radium therapy in these cases.

Irradiation Treatment of Malignant Tumors.—Alois Czepa (*Wiener klinische Wochenschrift,* September 11, 1924) states that the present day pessimism regarding the irradiation treatment of malignant tumors is not justified. Inoperable carcinomas and sarcomas, unless a severe grade of cachexia or multiple metastases render the prognosis unfavorable a priori, should be irradiated. The possibility of improving the conditions of life and of lengthening life are not so bad as is usually believed. It is absolutely necessary, however, that the treatment should be varied to suit the individual case. In addition to röntgen irradiation, general irradiations with artificial sunlight are indicated in order to build up the body strength.

Radiotherapy in Tumors of the Breast.—John F. Erdmann (*American Journal of the Medical Sciences,* December, 1924) emphasizes these points:

No tumor in the breast is a desirable tenant, even if its innocence be proved without a question of doubt. A growth in the remaining breast is as likely to be of primary origin as was that in the breast first removed. At the present day we are unable to state positively what the influence of röntgen ray and radium is either as a preoperative or postoperative aid. But in view of many apparent reductions in size, previous to operation in cases considered inoperable, the use of röntgen ray and radium should be encouraged until proved a menace. In my opinion too few years have passed for positive results to be shown even in view of some of the glowing reports at present regarding the nonrecurrence. Postoperative treatment should not be neglected by preoperative until some definite proof of its help or inefficiency has been established. In the presence of late metastases the powerful currents of the present day should be given a thorough test to prove or disprove the efficiency of this method of treatment. The most thorough and painstaking wide removal with remote glandular and fascial dissections will tend more and more to increase our percentage of cures and extension of life. The radical operation is attended with so low a mortality as to promote a greater desire on the part of consulting physician to demand early operation.

Use and Abuse of X Rays in the Treatment of Common Skin Diseases.—Earl D. Crutchfield (*New Orleans Medical and Surgical Journal,* January, 1925) says that the x ray is the most valuable of all the therapeutic agencies in dermatology but it is a very powerful and dangerous remedy unless used with discretion. However, if applied with care and accuracy, it is a most harmless agent. The fact that so many conditions respond to the x ray may often be a drawback, as the condition may be cleared up without ferreting out the etiological factors, particularly in those conditions where the etiology is obscure. Again, it is of extreme importance that no skin condition be treated without a reasonably sure or definite diagnosis being made. Unless this is conscientiously adhered to, erythema nodosum, pityriasis rubra, lupus erythematosus, rosacea, nevus pigmentosus, keratosis follicularis, or similar conditions, may receive x rays to no advantage. Lastly, the x ray is an important part of the dermatologist's armamentarium, but as a general rule never more than one skin unit should be administered within the period of a month, and only in exceptional cases should more than four units be administered.

Effect on the Blood of Irradiation, Especially Short Wave Length Röntgen Ray Therapy.—George R. Minot and Roy G. Spurling (*American Journal of the Medical Sciences,* August, 1924) studied the blood in forty-two cases, chiefly of cancer, before and after fifty-six röntgen ray irradiation treatments. Particular attention was given to the observations of twenty-two of the patients given thirty-six intensive short wave length treatments. The other irradiations were milder. Cases of disease of the hemopoietic tissue are not included and the statements below require modification when applied to such conditions.

The most important effect of customary therapeutic doses of irradiation on the blood elements is to decrease the number of white cells, especially lymphocytes, so that leucopenia and lymphopenia may occur. Preceding the decrease in the white count a transient increase develops, due to increment of polymorphonuclear neutrophiles. Very small doses of irradiation may permit a lymphocytosis.

When a customary therapeutic dose of short wave length röntgen rays is given, it causes the white count to reach its lowest point about six days later; at that time leucopenia is more often present than not. A decrease below normal of the absolute numbers of bone marrow white cells, which is indicative of marrow depression, is not unusual. Leucopenia lasts on the average about nine days, but may persist for over four weeks. If treatment is given again before the number of cells have remained for some time at their original level, leucopenia of a greater degree and duration is produced than after the first treatment. The fall in the lymphocytes is greatest in the first twenty-four hours, but they continue to drop for about three days. These cells rise with the white count, but do so proportionately more slowly. Subsequent treatments may keep the lymphocytes fewer in proportion to the white count than following the first irradiation.

The new short wave length röntgen ray therapy, suitably given, produces no changes in the blood that are of a different character from those occurring after milder yet intensive irradiation. However, it does produce more rapid, marked and persistent changes than milder treatment, and if the treatment consists of merely moderate long wave exposures it may not even cause a decrease of white cells.

An eosinophilia, of often seven and as high as twenty-three per cent. is usual two to three weeks after short wave length irradiation. It appears to develop particularly following repeated exposures. After irradiation the blood contains many degenerated white cells, especially in the first three days. There is scant mention in the literature of this feature of the blood in man. Larger doses produce greater numbers of these cells than smaller doses. After short wave length therapeutic irradiations the degenerated cells often amount to twenty-five to one hundred formed white cells.

Some increase of immature white cells may be observed, especially at about the time the white count begins to rise, after large doses of irradiation. A slight increase of the platelets soon after irradiation is common. They are depressed less readily than the white cells, but following the transient rise they are often found slightly decreased and rarely markedly. Combined with leucopenia they may be an indication of greater marrow depression than a decrease of only the bone marrow white cells. About four days after intensive irradiation and prior to a definite rise in the white count, the platelets rapidly increase and remain elevated above normal for days or weeks.

Important changes in the count of the red blood corpuscles and hemoglobin percentage do not occur as a result of mild or intensive therapeutic irradiation. Changes in the numbers of immature cells occur.

The clinical condition of the patient will influence the degree and duration of the blood changes after irradiation but anemia *per se* does not seem to be of any great importance. The white cells of patients whose clinical condition is similar, given the same dose in the same manner, show considerable variation. On the average, patients with higher white counts before irradiation will present leucopenia and marked lymphopenia less often than those with lower counts.

Much more important than the condition of the patient in determining the influence of irradiation on the blood is the size, intensity and character of the dose; larger doses producing greater blood changes than smaller ones.

The amount of surface area irradiated is a factor of great importance in determining the degree and duration of the decrease of white cells. The greater the surface area exposed to a given amount of irradiation the more profound on the average, is the effect on the white cells. Secondary radiation, which is greater with larger than smaller doses with short wave than long wave lengths, and with a large than a smaller portal of entry, probably plays a rôle in the production of blood changes.

Depression of the activity of lymphatic tissue and bone marrow are probably undesirable states, yet occur without obvious detrimental effect. The benefits derived from radiation appear to offset the production of leucopenia and lymphopenia.

Prior to irradiation the blood should be examined. In five thousand to the c.mm. or more, irradiation may be given without producing serious harm to the blood forming tissues. It is not ideal to give irradiation when leucopenia is present, but it may be done. With marked leucopenia repetition of treatment probably becomes a more serious event.

Before treatment is given to a patient with leucopenia a complete study of the formed blood elements should be made, for it may reveal a greater degree of marrow depression than expected and thus induce decision against irradiation. To determine whether or not to treat a patient with leucopenia one must decide whether the benefit of treatment will offset the disadvantages of an increased depression of the hemopoietic tissue. The latter may be of relatively little importance and distinctly less harmful than permitting a lesion to go untreated.

Radiation in the Female Breast Before and After Operation.—Walter E. Sistrunk (*Southern Medical Journal,* March, 1924) divides cancers of the breast into, 1, primary cancer of the breast, in which the palpable disease is confined to the mammary gland; 2, primary cancer of the breast, with palpable lymph nodes in the axilla; 3, primary cancer of the breast, with distant metastases; 4, recurrent carcinoma in the mammary area, with or without metastases; 5, distant metastatic carcinoma without local recurrence.

1. In primary carcinoma of the breast without palpable lymph nodes, we are justified in recommending a preoperative course of deep x ray therapy, to be followed in two or four weeks from the beginning of this treatment by surgical excision. The course of preoperative treatment will require a period of about ten days to two weeks, in order to avoid any constitutional symptoms. If the patient is from a distance and time is important, the operation can usually be performed within forty-eight hours after the last dose. With some risk of radiation sickness the treatment can be crowded into four to six days. The treatment so far as possible should be directed into the mammary tissues, the axillary and supraclavicular glands with the avoidance of the lung tissue so far as is possible if high voltage x rays are used.

2. In primary cancer of the breast with palpable lymph nodes in the axilla, the results of surgical treatment have been less satisfactory than in Group 1. In general, by surgical treatment alone the cures are estimated at from twenty to twenty-five per cent. These values can be doubled by adding preoperative and postoperative treatment. Unfortunately that still leaves a mortaliy of from

fifty to sixty per cent. In general, a course of preoperative radiation and operation should be given as soon as the constitutional effects have passed followed by a second course of radiation.

3. Primary cancer of the breast with distant metastases, such as involvement of the mediastinum, pleura, lungs, bone, liver, etc., is, so far as cure is concerned, hopeless from any known method of treatment. In some instances, the known local lesions can be made to disappear by radiation. Unfortunately, such lesions are usually only part of a general carcinomatosis. While such localized or known lesions are being treated the others are continuing to develop. If one is fortunate enough to get a case with the metastases localized to one or two lesions, he may succeed.

4. Recurrent carcinoma and known metastases can usually be made to disappear, but in most instances there will be ultimate failure. Patients, however, treated as long as fifteen years ago for recurrences, are still free from any known disease.

5. In the treatment of distant metastases without local recurrences, success can be hoped for only if they are strictly localized and not merely a part of a general carcinomatosis.

The author concludes as follows: Preoperative radiation treatment is intended to devitalize the carcinoma cells and to render the soil unfavorable for implantation. Postoperative treatment is intended to destroy any unremoved carcinoma cells and to destroy any neighboring metastases. The combination of surgery and radiation will probably double the good results obtained by surgery alone. Inoperable cases can sometimes be made operable by radiation. As much care and skill are required for the application of radiation as for excision by surgery. The possession of an x ray machine or of a quantity of radium is no more a guarantee of efficiency than is the possession of a set of surgical instruments a guarantee of surgical skill.

Ureteropyelography.—D. N. Eisendrath (*Annals of Surgery,* November, 1924) believes this procedure to be an important aid to abdominal diagnosis in general. It should never be employed in cases of acute renal infection or where a cystitis is so severe that even ureteral catheterization is a menace. The technic which is safest and most frequently employed is the following:

Preparation of the patient.—No special preparation aside from that incident to the radiography of the urinary tract is needed. Special stress should be laid upon the necessity of abstaining from the ingestion of food and of much liquid for six hours, at least, before the use of the sodium iodide solution. Even sterile water injected into the renal pelvis of some individuals will cause reflex nausea, vomiting and even symptoms of collapse, and these will be greatly decreased if the alimentary tract is empty.

Injection of the solution.—Too much emphasis cannot be placed upon the importance of injecting a solution warmed to near body temperature, slowly and with but little pressure. It is not necessary any longer in my opinion to employ the gravity method nor to insert a manometer between the syringe and ureteral catheter. First aspirate the contents of the renal pelvis and then inject seven to ten c.c. of the solution with an ordinary Luer syringe after having introduced a No. 5 or No. 6 ureteral catheter whenever possible as high as the renal pelvis. The best indications that enough solution has been injected to distend the renal pelvis is the degree of resistance to any further injection. If the patient does not complain of pain and there is no resistance, it is perfectly safe to continue to use more of the solution until there is distinct resistance or one can stop when fifty or sixty c.c. have been injected, to take the first picture and wait until it is developed before injecting any more solution.

The first exposure is made while the catheter is inserted either into the renal pelvis or lies at the level of an obstruction in the ureter. The catheter is next withdrawn until it lies near the lower end of the ureter and a second exposure made after injecting enough solution until resistance is again encountered. The third exposure is made about one hour, if possible, after the first one to ascertain whether there is any retention in the renal pelvis or ureter as is so often seen in cases of ureteral stricture. Ordinarily we only make exposures when the patient is in a horizontal position, but if there is any suspicion of a movable kidney, the patient must be raised to the vertical position by elevating the x ray table at one end before the catheter is withdrawn from the ureter in order that an exposure may be made to determine the degree of mobility of the kidney and a kinking of the ureter. If possible all of the solution should be permitted to escape before the ureteral catheter is withdrawn. Do not hesitate to make a bilateral exposure at the same sitting, provided that the solution is allowed to escape or is aspirated from one side before the second is injected. An unobstructed renal pelvis or ureter empties within a few minutes as one can readily observe if a series of exposures are made at the same sitting.

Röntgen Ray Intoxication.—S. L. Warren and G. H. Whipple (*Journal of Experimental Medicine,* December, 1824) state that a suitable dose of x ray will destroy in large measure the epithelium lining the crypts and covering the villi of the small intestine, leaving empty crypts and naked villi exposed to swarms of bacteria in the intestine. The outstanding feature of the experiments described on dogs is the striking contrast between obvious injury of the intestinal epithelium and the lack of invasion of the intestinal bacteria into the tissues, lymph or blood. Apparently, therefore, the intestinal epithelium is not the all important barrier which protects the tissues from invasion by intestinal bacteria. The authors believe that the experiments described indicate that the hard x rays which injure the epithelial cells of the intestine travel in straight lines through the host's tissues with no evidence that these rays are deviated to injure tissues outside of the direct x ray pathway.

Treatment of Inflammatory Diseases of the Genitals with Ultrasun.—G. Haselhorst and Fr. Peemöller (*Zentralblat für Gynäkologie,* February 16, 1924) report that the treatment of adnexal tumors with the ultrasun is applicable only in subchronic and chronic cases. The good results in some cases cannot be denied, but they are not particularly striking and they can be achieved just as well and to the same extent with other more simple methods. The ultrasun is practically free from the danger of burns because it emits rays that lie within the biologically stimulating portion of the ultraviolet rays, namely, between wavelengths of 313 and 297, which contain very slight intensities of light in comparison with the artificial sun lamp. They good results in some cases cannot be denied, but they are suitable for irradiation of serous and mucous membranes. This effect is accomplished through the relatively slight intensity of the current and through the addition of metallic salts (probably combinations of nickel and cobalt) to the carbon electrodes.

Rôle of the Liver in General Röntgen Injury of the Body.—Paul Neuda and Fritz Redlich (*Wiener klinische Wochenschrift,* November 1, 1924) are enabled to show that röntgen rays have a very definite action upon albumin, which is recognized, among other signs, by the displacement of chlorides in the organism. In normal individuals, especially in those having a healthy liver, this process goes on without any special disturbance and the excessive chlorides are excreted by the kidneys; if this regulating process does not take place (as in relative or absolute insufficiency of the liver), there results, for reasons not as yet entirely explained, a disturbance in the physicochemical equilibrium of the blood colloids with its symptomatology, including a reduction in the number of leucocytes, a diminution in the blood pressure, a change in the time of coagulation and of the refractometric index, as well as a diminution of the chlorine content of the blood. These changes result in the symptomatology of severe general röntgen ray injury of the body.

Fulguration of Hunner Ulcers.—H. Dawson Furniss (*American Journal of Obstetrics and Gynecology,* March, 1924) concludes as follows: 1. All possible foci of infection should be removed. 2. Resection is a formidable operation with at times spectacular and at times dismal failures. 3. Fulguration is a simpler method of dealing with the problem and should be tried first. 4. The results are frequently most gratifying. At least, temporary relief can be counted upon, and if there is recurrence the ulcer can be fulgurated again. The willingness of the patients to submit to second and third fulgurations is a convincing testament of the relief they receive. 5. Until something better is discovered fulguration should be continued. 6. The greatest relief and best looking bladders are those in which fulguration was the most thorough, and performed under sacral anesthesia through the air distended bladder. 7. With increased experience and perfection of the technic even more satisfactory results may be anticipated.

Measurement of Ultraviolet Light.—A. Webster, Leonard Hill and A. Eidinow (*Lancet,* April 12, 1924) recommend the measuring of ultraviolet light with the use of a standard acetone methylene blue solution and a standard quartz tube having an internal diameter of three mm. This is filled with a solution consisting of two parts of standard methylene blue solution and one part of acetone. The method of measuring is described in detail.

Röntgen Diagnosis of Postoperative Ileus.—J. T. Case (*Annals of Surgery,* May, 1924) emphasizes the statement that the suggestion of this x ray method for establishing a diagnosis of ileus is not intended to serve in any way as a substitute for the other clinical methods already in general use, but this x ray examination, carrying with it so little disturbance to the patient, requiring no preparation, and often giving much important help, is suggested as just one more means of diagnosis in the hope of reaching more quickly a definite decision. This report is based upon an extensive postoperative x ray study covering several hundred patients, the great majority of whom had no untoward symptoms during their postoperative course, the examination being made to establish the normal postoperative behavior of the bowel and to serve as a basis for the conclusions above expressed concerning the value of the x ray study in the early diagnosis of postoperative ileus.

Use of X Rays in Antenatal Work.—Edward W. H. Shenton and Charles H. S. Horowitz (*Lancet,* February 16, 1924) now use röntgenography in any case about which there is any doubt in a primipara where the head is still above the brim of the pelvis during the last two weeks of pregnancy. When the röntgenograms show an adequate disparity between the fetal head and the pelvis the patient is allowed to go on to labor. The authors have had few disappointments with this procedure. By taking a plate at a different angle, so that a view is obtained more directly down into the pelvis instead of a merely transverse view of the inlet, the physician will not be misled by a well marked promontory of the sacrum. Röntgenograms can also be obtained now of the outlet of the pelvis. The plate also gives some idea of the amount of ossification of the head, which also helps in determining when the fetus is overdue. Pelvimetry is no longer necessary, for what really matters are not the absolute but the relative measurements of the head and pelvis, and these are readily seen in the röntgenogram. There is not the slightest risk to mother or child. Newborn babies show complete immunity to ordinary x ray exposures and therefore these need not be feared. Another advantage is the elimination of the disagreeable manual manipulation. The time of ossification varies considerably. Stereoscopy enables us to see the fetal head and the surrounding bones in relief.

What the Practitioner Should Expect in X Ray Diagnosis.—F. B. Stephenson (*Colorado Medicine,* August, 1924) presents the following list of "don't expects" and says that the practitioner can expect almost anything in x ray diagnosis which is not included.

Don't expect an unqualified diagnosis of early brain tumors.

Don't expect cartilage to show as such.

Don't expect ruptured ligaments to show as such.

Don't expect nerves to show.

Don't expect diagnosis as to the character of pelvic tumors.

Don't expect a differential diagnosis between a large empyema and hydrothorax.

Don't expect gallbladder pathology to be demonstrated in every case.

Don't expect a diagnosis of pregnancy under three months.

In general don't expect diagnosis of diseases which cause no major organic change. Acute chest diseases cause definite changes which give distinguishing shadows.

Don't be afraid of incurring x ray burns in diagnostic work.

Don't fear injury to the retina and optic nerves or other nerves from radiographic exposures. Even in treatment work nerve tissue has proven very much more resistant than other body tissues.

Finally, and very important, don't expect an accurate diagnosis of fractures by fluoroscope only. It shows only major details. Small fractures, "greensticks" and impactions are not dependably examined without plates. In fact, no fracture is adequately shown fluoroscopically.

Diagnosis of Tuberculous Spondylitis in the Röntgenogram.—H. J. Schmidt (*Schweizerische medizinische Wochenschrift,* August 28, 1924) asserts that few of the roentgenological signs of tuberculous spondylitis are pathognomonic. The early stages of the disease cannot always be recognized on the plate. In the presence of caries at the level of the thoracic vertebræ, eighty per cent. of the cases show suppuration at the necropsy, sixty-six per cent show the presence of abscess roentgenologically, while only twenty-five per cent. can be recognized on purely clinical grounds. An absolute roentgenological diagnosis can be made only in the late stages. It is only rarely that the roentgen diagnosis cannot be made for one to two years and in the large majority of cases the roentgenogram is characteristic after four to six months.

Animal Tumor Cells Made Resistant to X Rays by X Rays.—S. Russ (*Lancet,* March 22, 1924) found that by subjecting tumor cells to increasing doses, a number of steps in the action which x rays have upon these tumor cells beginning after moderate doses with a slowing up of its normal rate of growth, can be discerned. With greater doses the tumor acquires an increased resistance to the x rays. When doses very near to the lethal dose are given degenerative features appear in the cells which can be recognized microscopically.

Asthma and Hyperthyroidism Treated by Radiotherapy Over the Thyroid Gland.—F. Widal and P. Abrami (*Presse médicale,* May 31, 1924) bring forward fresh proof in support of their belief in the endocrine origin of certain forms of asthma. The four cases they report present a striking analogy. All are cases of essential asthma, independent of any detectable alteration in the respiratory apparatus, and occurring in women who present the typical picture of Basedow's disease. These four patients improved remarkably and were perhaps cured by radiotherapy over the thyroid body.

RESPIRATORY DISORDERS

Pneumonia in Children.—William T. Freeman and Lewis D. Hoppe (*American Journal of Diseases of Children,* September, 1924) report twelve cases of pneumonia in infants and children treated by intravenous injections of mercurochrome—220 soluble, together with animal experimentation, showing that following the injection of mercurochrome the fluid squeezed from the lungs inhibits the growth of bacteria.

Of the twelve cases of pneumonia, seven were bronchopneumonia and five were lobar in type. Two patients died. In one, death was inevitable before the drug was given. In the other case, with cyanosis of unknown origin existing for several years, the patient showed definite improvement at first but later failed to respond to treatment. In seven cases one injection was all that was required. Three cases required two injections and in two cases three injections were given. The average dose was 0.005 gm. to the kilogram of body weight, using a one per cent solution.

Marked clinical improvement usually occurs a few hours after the injection, and this improvement sometimes occurs without any marked change in the temperature or pulse rate. These cases of pneumonia treated with mercurochrome ran a much shorter course than cases of pneumonia of the same severity where this drug was not used. The systemic reaction is mild in children. The results obtained by this drug are often spectacular. The course of the disease is sometimes shortened and often abruptly terminated.

Adrenalin Applied to the Larynx in Grippe Croup.—In influenza croup there is a high grade of hyperemia of the small bloodvessels and capillaries with edema and almost no exudative processes. On the basis of the fact that adrenalin produces an anemia and detumescence of tissue in mucous membranes and wounds, W. Arnold (*Monatsschrift für Kinderheilkunde,* September, 1924) tried the use of adrenalin in severe cases of grippe croup at the site of the swelling directly, namely, the entrance to the larynx, as repeated subcutaneous injections of adrenalin as well as inhalation of adrenalin did not produce the desired results.

The technic is as follows: A piece of cotton as large as a bean, with a cord attached and pulled under the nail of the index finger, was moistened with 0.5 to 1.0 c.c. of 1:1000 adrenalin solution. The cotton was then inserted in the same manner as the procedure of intubation is carried out. The index finger of the other hand is used to depress the

ase of the tongue to prevent the contamination of the adenalin with mucus. The cotton is pushed past the epiglotis and applied to the vocal cords with slight pressure, so hat the adrenalin also reaches the deeper parts of the larynx, whereupon the attack of coughing shows that it is properly pplied. The mucus from the pharyngeal wall should be riped away.

This test may also be used as a differential sign between rippe laryngitis and laryngeal diphtheria, as the stenosis a diphtheria does not recede after the local application of drenalin. Diphtheria is chiefly an exudative process, whereas the exudative process is practically missing in grippe roup. In the latter the adrenalin produces anemia and etumescence, which is not the case in diphtheria. Even hough the result is only a momentary one, the author had to epeat the adrenalin treatment only once in his cases.

Precipitation of Crises in the Treatment of Pneumonia.—F. M. Gardner-Medwin (*British Medical Journal,* July 12, 924) advances the following conclusions:

1. Pneumonia is the result of lowered resistance.

2. Lowered resistance is coincident with, if not caused by, eucopenia.

3. Leucopenia is the result of a toxin, which temporarily paralyzes the power of the system to respond to the chemoactic call of bacterial invasion.

4. Sodium nucleinate, injected intramuscularly, has the power to overcome this disability and to call out the reserves of leucocytes stored in the marrow, converting the leucopenia into a leucocytosis, thereby precipitating the devolution of the disease.

5. The effect of sodium nucleinate is independent of the duration of the illness, provided the patient is not in a dying condition before it is administered.

6. The action of this remedy is greatly facilitated by intensive alkalinization of the system by the administration of large doses of sodium bicarbonate.

7. Lobar pneumonia reacts more typically and satisfactorily than does bronchopneumonia.

Lipiodol in the Diagnosis of Bronchiectasis.—P. F. Armand-Delille and Alan Moncrieff (*British Medical Journal,* July 5, 1924) obtained clear röntgenograms of the bronchi by previously injecting lipiodol into the bronchi. Bronchial dilatation of even slight degree is definitely shown and localization of vague shadows becomes very much simplified. Cases of frank tuberculosis should not be submitted to this method, for the resulting congestion may be harmful. In many cases its use is invaluable. The lipiodal is injected into the trachea through the cricothyroid membrane under novocaine anesthesia. About ten c.c. are necessary to inject the bronchi of a child seven to fourteen years and the injection is made at the rate of three c.c. a minute. The röntgenogram is then taken immediately after the injection.

Epidemic Pleurodynia.—David Greene (*Archives of Pediatrics,* May, 1924) describes an epidemic disease which, because of its symptomatology, may best be called epidemic pleurodynia. This condition is characterized by the sudden onset of pain in the chest or upper part of the abdomen, fever and moderate prostration. Its etiology and nosology cannot be definitely stated. There are, however, several features about the disease—its epidemicity, abrupt onset, cyanosis, one to three days fever, leucopenia and moderate prostration—which somewhat resemble influenza. On the other hand, the acute pain in the chest which is the most striking symptom and the absence of generalized aches and pains and the absence of an inflamed nasopharynx are atypical of influenza.

The Common Cold.—R. L. Cecil (*Medical Clinics of North America,* July, 1924) emphasizes the value of general hygienic measures in the prevention of acute respiratory infections, such as raising the vitality of the patient, the avoidance of gastrointestinal disturbances, proper ventilation of the rooms, suitable clothing, the removal of focal infections, and the care of the circulatory and nervous systems by massage, baths and exercise. The patient's resistance is best raised by the use of autogenous vaccines.

The treatment of an existing cold includes certain fundamental principles: 1, rest, preferably in bed; 2, simple diet; 3, catharsis; 4, the use of mild analgesics, such as aspirin or pyramidon. The old fashioned treatment, consisting of hot bath, lemonade and whiskey, and a full dose of Dover's powder, still has many advocates. Locally, the author employs a twenty-five per cent. aqueous solution of argyrol and it should also be used as a gargle. Quinine is not very efficient. Vaccines have no value in the treatment of an actual attack. The results with the chlorine gas treatment with an atmosphere containing 0.02 mg. of chlorine to the litre were satisfactory in acute and chronic rhinitis, influenza and whooping cough; better results were obtained in acute laryngitis and acute bronchitis.

Pneumonia from the Viewpoint of the General Practitioner.—S. B. Wolff (*New Orleans Medical and Surgical Journal,* July, 1924) bases his treatment on an attempt to overwork the three channels of elimination, the skin, bowels and kidneys, thereby saving the lung until the crisis or lysis. The patient is kept in a well ventilated room, avoiding extremes of cold. When seen early a calomel and soda purge is ordered, with podophyllin added in case of great constipation. Hot mustard footbaths are ordered with minute instructions as to their administration so as to bring about perspiration. Soda citrate in from fifteen to thirty grain doses every two hours furnishes an alkaline diuretic and a mild diaphoretic. Quinine is given to adults, twelve to fifteen grams a day, and its effect on the temperature noted; if it is found beneficial it is continued, otherwise discontinued. If there is no change in temperature conditions on the fifth or sixth day it is well to be suspicious of complications, such as nonsymptomatic otitis media or pyelitis, especially in children; for the former an aural examination is necessary, for the latter, citrate is discontinued and urotropin ordered. A mild cough mixture is given when the cough is annoying, but properly administered hot mustard baths serve as sedatives, especially in children. In the early stages aspirin is of service, in conjunction with an ice cap, to reduce fever. The writer has not used digitalis much, but has no objection to it, as it is a good heart tonic and a useful diuretic. Strychnine is also of service as a general tonic. Diet should be light and nutritive; liquids, such as broth, fruit juices, malted milk, and the various mixtures of alcohol and beef juice. Nourishment is ordered every two hours.

Vaccine Treatment of Ozena.—Kozo Sagakami (*Lancet,* June 7, 1924) draws the followng conclusions from the experimental results obtained so far: As various diseases of the nasal passages present a close resemblance to ozena, the effectiveness of the vaccine treatment of ozena patients can only be determined by applying the autogenous vaccine produced from the bacteria carried by the patient himself, and after the species of such bacteria have been ascertained. Bacteriological observations show that most ozena patients suffer from a mixed infection by the coccobacillus and gram positive mucus producing bacilli; therefore the application of mixed vaccine derived from these two kinds of bacteria appears reasonable. Injections of coccobacillus vaccine and mixed vaccines are the most reasonable treatment of ozena cases. Ozena patients generally show a decreased number of red and white corpuscles, and this condition does not change after vaccine treatment.

Vaccines in the Treatment of Purulent Pleurisy.—G. Vallet and A. Augé (*Bulletin de l'Académie de médecine,* July 29, 1924) report twelve cases of purulent pleurisy, of which eleven were known to be streptococcic, met with during an epidemic of grippe. Of the six who did not receive vaccine, but were treated by ordinary procedures, four died; in three of these an operation had been performed. All of the six cases treated with vaccine recovered; three of these cases were operated. The vaccine used was an autogenous preparation from cultures on bouillon with ascites fluid; after centrifugation the germs were diluted to 500 millions per mil in chloroform water. The number of injections, except in two cases, ranged from five to nine; one to two mils were given each time. In the two other cases, as an emergency measure, "ptysmatherapy" was practised, a suspension of the patients' sputum in chloroform being administered at the start and treatment then continued with a vaccine. In the last two cases treated a pyovaccine was prepared at the bedside by suspension of two to three mils of freshly withdrawn pus in a little chloroform. In both cases the condition cleared up almost immediately after the injection. The writers conclude that vaccine therapy is a valuable therapeutic agent in purulent pleurisy. It enables the surgeon to select the time of operation so that it shall be performed under the most favorable conditions, that is, when the general manifestations and pulmonary lesions have definitely improved.

Medicolegal Notes.

RIGHT TO ENJOIN COMPETITION ON TERMINATION OF ASSISTANT'S CONTRACT

The Minnesota Supreme Court holds, Granger v. Craven, 199 N. W., 10, that it is but a reasonable protection of a legitimate interest for a physician and surgeon, having a long established practice, to require of one whom he is about to employ as an assistant in such manner as to give him access to the acquaintance and confidence of patients, a covenant not to enter into competition with the employer for a reasonable time after the relationship is terminated. Where, in such a case the assistant covenants, in the event of the termination of the employment, not to open an office in the same city (containing not over 20,000 population), nor within twenty miles thereof, for a period of three years, it was held that the protection was reasonable and the covenant might be enforced by injunction. The court also says in its syllabus: "Where a professional man is employed to take over an entire department of the employer's practice, it is so clear that he will acquire the confidence and adherence of many of the patients that irreparable damage to the employer will be presumed to arise from the employee's breach of the covenant not to establish a competing practice for a period of three years. Relief in such a case will not be denied because the employer had the right to terminate the contract at any time upon thirty days' notice, the employee having the same right and the contract having been performed and the employment under it continuing for over two years."

LEAVING SPONGE IN WOUND HELD NEGLIGENCE

The Texas Court of Civil Appeals holds Moore v. Ivey 264 S. W., 283, that where, in a malpractice case, the jury found, upon sufficient evidence, that the defendant left a sponge in an incision in plaintiff's body after an operation warranted a further finding that such act constituted negligence on the part of defendant.

EVIDENCE AS TO LEAVING GAUZE SPONGE IN WOUND

The Oklahoma Supreme Court holds, Mayberry v. Myers, 229 Pac., 563, that the general rule that, in law actions, sought to be reversed on the sole ground that the evidence was insufficient to support the verdict, the judgment will be affirmed where there is any evidence reasonably tending to support the verdict, is applicable in an action for failure to remove a gauze sponge from the abdominal cavity after performing a surgical operation and before closing the incision, where the operation was performed by the surgeon in his own hospital and surrounded by nurses in his employ and associate physicians.

PRIVILEGE STATUTE NOT WAIVED BY PLAINTIFF'S TESTIMONY

The Minnesota statute, §8375, G. S., 1913, forbids a physician from disclosing, without the consent of his patient, information acquired in his professional capacity and necessary to enable him to act in that capacity. The Minnesota Supreme Court holds, Polin v. St. Paul Union Depot Co. 199 N. W., 87, that a plaintiff did not waive this privilege by bringing an action to recover for injuries, and testifying at the trial as to the injuries and that a broken bone in his leg had been set and the leg placed in a cast by the physician.

REGENTS OF STATE UNIVERSITY HELD NOT LIABLE FOR NEGLIGENCE OF EMPLOYEES OF UNIVERSITY HOSPITAL

The Michigan Supreme Court holds, Robinson v. Washtenaw Circuit Judge, 199 N. W., 618, that the regents of the University of Michigan were not liable for the negligence of a surgeon resulting in injuries to a surgical patient in the University hospital, by permitting a sponge to remain in a wound, under the rule that charitable institutions supported wholly or in part by a state or municipality are not liable for personal injuries suffered through the negligence of an employee, servant or agent of thei nstitution. The hospital is an adjunct of the medical department of the University, which is a state educational instrumentality maintained by the public at public expense, controlled and operated by the Board of Regents, a governmental agency which receives in trust and expends the public money devoted to that purpose. The court was of opinion that denial of liability as to the regents could safely be rested either on the ground that the institution was a state instrumentality or that it was a charitable institution.

STRAIN AGGRAVATING HERNIA NOT WITHIN ACCIDENT POLICY

The South Carolina Supreme Court holds, Young v. Continental Casualty Co., 122 S. E. 577, that the direction of a verdict for the insured in an action on an accident policy for an injury resulting in hernia, claimed to have been caused by an unusual strain in reaching up to get a book down from a high shelf was error in view of the plaintiff's admission showing the presence of hernia six months before. If a person suffering from some weakness or disease subjects himself to conditions which would not injuriously affect persons in ordinary health, but should be dangerous to him, it would not be due to an accidental cause.

SICKNESS FROM INHALING IRON DUST FROM LATHE

The Illinois Supreme Court holds, Peru Plow & Wheel Co. v. Industrial Commission, 311 Ill. 216, 142 N. E. 546, disability arising from an employee's continued breathing of iron dust in his particular occupation of operating a lathe used in boring out or enlarging the inside of metal wheel hubs, where there was not one circumstance, incident or time showing the starting place of the disability, was not the result of an accident but of an occupational disease.

CAUSE OF LOSS OF EYE, DISEASE OR HEMORRHAGE FROM STRAIN

In proceedings for compensation for injury to claimant's left eye, alleged to have been caused by strain in doing some heavy lifting, or in wielding a heavy hammer, causing hemorrhage in the eye, resulting in the loss of the sight thereof, one physician testified that the causes alleged could be the immediate cause of the hemorrhage which he discovered on examination. Two physicians, who also examined the plaintiff at other times testified that they did not discover any hemorrhage in the eye, and that, in their opinion, the condition of the eye was the result of disease and not the result of hemorrhage.

The Indiana Appellate Court, J. H. Hardin Co. v. Crowe 143 N. E. 710, said that were it permitted to weigh and decide in accordance with the preponderance of the evidence it might reach a conclusion different from that of the Industrial Board, which awarded compensation; but, as the award was sustained by competent evidence, the Supreme Court on appeal is not permitted to weigh evidence.

FIBROID TUMOR NOT COVERED BY POLICY EXCEPTING DISEASE NOT COMMON TO BOTH SEXES

The Georgia Court of Appeals holds, Riley v. American Nat. Ins. Co., 123 S. E. 33, that a health and accident policy providing that it did not cover any loss resulting from any disease "not common to both sexes" did not cover a fibroid tumor, the undisputed evidence being that men cannot have fibroid tumors.

The Mechanism of Disease

A Preliminary Communication

S. D. LUDLUM, M.D.
and ELLICE McDONALD, M.D., F.A.C.S.
Philadelphia, Pa.

The treatment of disease has been always empirical and, although facts about disease have been discovered, there have been few fundamental biological principles as yet laid down for disease processes, or for the mechanism of drugs. A drug was used because experience proved its value, not because its mechanism was known. Our aim in this paper is to report a preliminary communication of our method for the study of disease, biologically considered.

The study of disease is the study of the reciprocal relation of the apparatus, protoplasm and the force, energy. The unit of protoplasm is the cell. The apparatus, protoplasm, by its reactions, produces the changes and activity which result in the body processes. All action of protoplasm depends upon the energy content of its molecules and protoplasm is nothing more than an apparatus for transforming energy into living processes. The availability of the energy depends upon the requisite configuration of electrons in the atoms of the substances, inorganic or organic, introduced into the body cells and medium from the environment.

All energy comes from the sun by means of plants, (chlorophyll) and animals which live on these plants, and is absorbed into the human system as food, carbohydrates, proteins, lipins, etc. These substances are most of them nonpolar and become polar when they are associated with inorganic substances or other polarizing substances, as in the processes described by Donnan's law of membrane equilibria.

The action of those polarized substances depends upon the amount of basicity or acidity—the hydrogen ion concentration. To quote Loeb (1), "The results of our work lead to the conclusion that there is only one source of colloidal behavior, namely the Donnan equilibrium." (p. 285.) Again, "When a colloid substance used is an amphoteric electrolyte, the addition of a little acid or alkali to the isoelectric substance increases the osmotic pressure, the potential difference, viscosity, stability of the solution and the swelling of the gel." (p. 277.) It is quite possible that Loeb's conclusions are too sweeping in regard to the processes of Donnan's equilibrium, but there is no doubt that he is right in the main and that the key of human protoplasmic behavior is that of action upon the semipermeable cell membrane or surface film of the colloid emulsoid system.

Donnan's law is as follows: When a membrane separates two solutions of electrolytes, one of which contains one ion which cannot diffuse through the membrane, while all the other ions can diffuse through the membrane, the result will be an unequal distribution of diffusible ions on the opposite sides of the membranes. At equilibrium, the products of concentrations of each pair of oppositely charged diffusible ions are the same on opposite sides of the membrane (such as cell membrane). This unequal concentration of the diffusible crystalloidal ions must give rise to potential differences, and osmotic forces which furnishes the explanation of colloidal behavior.

Colloid substances (and the protoplasm of the body must be considered as a polyphasic colloid system of the emulsoid type) are altered in their behavior by the relation of acids and bases. Bases and acids are considered, in our study, according to the definition of Lewis (2) that "a basic substance is one which has a lone pair of electrons which may be used to complete the stable group of another atom, and that an acid substance is one which can employ a lone pair of electrons from another molecule in completing the stable group of its own atoms, "or the basic substance furnishes a pair of electrons for a chemical bond, the acid substance accepts such a pair." (p. 142.)

The influence of basicity and acidity may be seen in the case of the substance $C_6H_5So_2OH$ which may be regarded as a derivative either of sulphuric or sulphurous acid, namely, a, sulphuric acid in which one hydroxyl group is replaced by phenyl, b, sulphurous acid in which one hydrogen is replaced by phenyl. In accordance with assumption, a, we should assign to sulphur the polar number +6 and to phenyl as a whole, the polar number —1. With assumption b, we would give +4 as the polar number of sulphur and +1 as that of phenyl. Now, it is usually taken for granted that, on hydrolysis, a positive atom adds hydroxyl and a negative atom adds hydrogen, but, when we apply this criterion to the case before us, we find the substance hydrolyzes in acid solution to give benzene and sulphuric acid, and, in a basic medi-

Copyright, 1925, by A. R. Elliott Publishing Company.

um, it gives phenol and subphurous acid (v. Lewis, p. 70). Many other examples of such influence of the action of basicity and acidity may be given, as the action of phosphoric acid as a monovalent, bivalent or trivalent acid under different conditions.[1]

The bases, acids and salts of the body thus affect the colloids of the protoplasm and this influence is in a definite order according to their surface tension and other intrinsic properties.

Besides the number of charges carried by the ion, the efficiency of the ion is measured by the voltage of the ions, that is, by the tendency of the ion to give up its charge or by the amount of available energy of the ion. There are always two factors in energy, the quantity factor, and the intensity factor. Just as in an electric current, the amount of work it can do is measured by the amount of current and the voltage, so, in an ion, the amount of work it can do is measured by the number of charges and by the voltage or intensity factor of the charge.

The intensity factor in the human system is the hydrogen ion concentration, or pH (hydrogen potential) and the quantity is the polar substances, the inorganic salts of the cells and serum, which produce the polarization of the colloid substances. Blood must be considered only as a more mobile form of body tissue, but still a colloid emulsoid system.

There are then, three factors in the energy side of the problem—the inorganic salts, the hydrogen ion concentration, or to use loose terms, the basicity or acidity and the food source of the energy which must be made available by the first two in the process called metabolism.

These factors influence the unit of the body, the cell, so that it becomes more or less permeable, has more or less viscosity, has more or less conductivity, increases or decreases in osmotic pressure and in swelling or contraction accordingly as it does in experimental colloidal solutions.[2]

The cell is influenced in one direction or another, and, in the human body, this influence, according to our researches, is directed through the vegetative nervous system, the vagus-sympathetic anion-kation balance.

This is the mechanism whereby the changes in body salts and hydrogen ion concentration modify the energy derived from outside sources (the food, etc.) to accompany the changes in the cell, and, with these changes, alteration in the protoplasmic metabolism and body processes. The anion state is reciprocally correlated with the vagus state and the kation with the sympathetic state.

The vegetative nervous system, as is well known, controls the unconscious processes of the body, the lungs that breathe, the heart that beats, the kidneys that secrete, the intestines that move, and the osmosis in the cell is coincidently altered. The processes of the vegetative nervous system can best be studied in the action of the smooth or involuntary muscle over which it has direct control. The striated muscle of the heart is involuntary muscle, and is, indeed, a variety of smooth muscle. The vegetative nervous system consists of two parts, the vagus and sympathetic. The vagus inhibits the heart and stimulates the action of the intestines and pupil. The sympathetic stimulates the heart and inhibits the action of the musculature of the intestine, but stimulates the intestinal sphincters.[3]

These cells of smooth muscle act and react as do single cells used in biological study and the action of the smooth muscle of the intestine gives the direct index of metabolism and physiological processes. The action of the smooth or involuntary muscle of the body may be studied in the pupil, the heart and the intestine. In our study, we have found that it is best studied in the action of the stomach and intestines, the largest unit of smooth muscle in the body and capable of great changes and alterations, as viewed by the fluoroscope and recorded by radiographs after the barium sulphate meal. The rhythm, rate and amplitude of the stomach and intestines may be studied and recorded under uniform conditions, and, in the absence of drugs, purgatives, or other substances, so give a record and estimate of the varying influence of the vagus and sympathetic parts of the vegetative nervous system. These findings may be correlated with observations upon the heart, temperature, hydrogen ion concentration of the blood, reaction of the urine, stool and saliva, blood examinations and other materials, all of which we have found of use in the estimate of the action of energy and its influence upon the vagus-sympathetic balance in metabolism and disease. Blood chemistry, particularly nonprotein nitrogen and plasma protein estimation, is also of value. The reactions of the stool and mouth we consider suggestive.

TYPICAL KATION OR SYMPATHETICOTONIA	TYPICAL ANION OF VAGATONIA
Decreased smooth muscle reaction	Increased smooth muscle reaction
Higher pH	Lower pH
Alkaline mouth	Acid mouth
Alkaline stool	Acid stool
Alkaline urine	Acid urine
Barium retained in colon	Barium passes out quickly
Constipation	Spasticity of colon
Morning temperature lower than normal (when no infection)	Morning temperature higher than normal (when no infection)
Higher blood pressure	Lower blood pressure
Higher pulse rate	Lower pulse rate
Regular pulse	Arrhythmia
Higher red cell count	Lower red cell count
URINE	URINE
Chlorides lessened	Chlorides increased
Albumin	Small amount albumin
Higher specific gravity	Lower specific gravity
Lowered sugar tolerance	Higher sugar tolerance
Lessened urine output	Increased urine output
Warm hands	Cold hands
Large pupil	Small pupil

[1]Examples and explanation of this may be found in the books of Lewis and J. Loeb and in the writings of Langmuir, *J. Am. Chem. Soc.* 1916, 38,22: I, 1919, 41, 868: II, 1919, 41, 1543 and 1920, 42, 274.

[2]These phenomena may be well understood by reference to J. Loeb's book, *Protein Behavior*, to the book *General Cytology*, University of Chicago Press, 1924, written by the biologists who spend the summer at Woods Hole, Mass., edited by Cowdry, to the book of R. S. Lillie, *Protoplasmic Action and Nerve Action*, University of Chicago Press, 1923, to Mathews' book *Physiological Chemistry*, Wm. Wood and Co., New York, 1921, to Osterhaut's book, *Injury, Recovery and Death*, to the writing of Dr. True, professor of botany in the University of Pennsylvania, and to the latter we wish to express our thanks for encouragement and assistance in the colloid problem.

[3]The study of the vegetative nervous system and its action may be found in the works of Heinrich Higier, *Vegetative Neurology*, Nervous and Mental Disease Publishing Co., New York, 1919; Eppinger and Hess, *Vagatonia*, Nervous and Mental Disease Publishing Co., New York, 1915; Sherrington, *The Integrative Action of the Nervous System*, Yale University Press, New Haven, 1920; W. Langdon Brown. *The Sympathetic Nervous System in Disease*, Oxford University Press, 1920; W. H. Gaskell, *The Involuntary Nervous System*, Longmans Green, 1916.

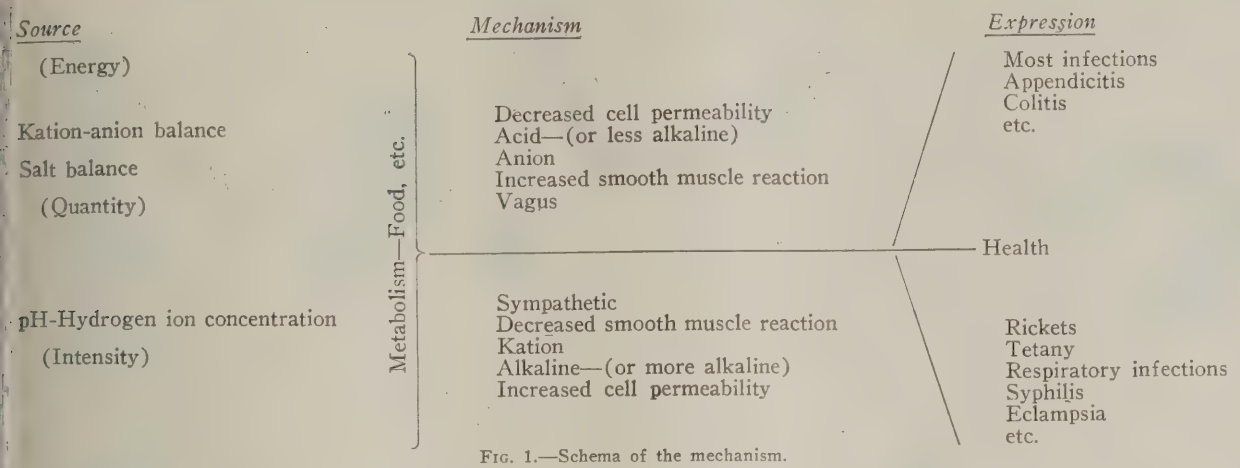

FIG. 1.—Schema of the mechanism.

In the division between the kation and anion sympathetic-vagus state, dependence is not put alone upon these criteria, but the following clinical signs are also of value. It must be understood that these signs are those found in the typical or extreme kation and anion conditions and that all intermediate grades are found. The smooth muscle reaction is the most delicate and accurate of these tests.

We have found from a study of the rhythm, rate and amplitude of the intestine and stomach that these vary in direct proportion to the hydrogen ion concentration of the blood and we show this in x ray pictures, and that changes can be produced in the intestine by the injection and ingestion of various salts of sodium, potassium, magnesium and calcium, as shown by the accompanying radiographs. Chemical variations in the body fluids can affect the vegetative nervous system and, in this way, the entire system of smooth muscle in the blood vessels, heart, and digestive tract.

In our x ray pictures, being still pictures, it is possible to show only the amplitude of the large intestine which corresponds with the hydrogen ion concentration of the blood. The rate apparently goes, more or less, with the force, while the rhythm appears to be governed by both these facts. The fluoroscopic study is equally important with radiographic record.

We have also found that certain diseases show changes in the large intestine and hydrogen concentration of the blood according to vagus or sympathetic preponderance and that these diseases may be classified into one or other group according to such preponderance of one or other part of the vegetative nervous system.

The proper balance of the vegetative nervous system is necessary to health and is an expression of profound body changes in the cell protoplasm. Disease is the deviation from this balance and is an expression of the changes in the apparatus, protoplasm, and the force, energy, and these changes may be recorded through the action of the smooth muscle of the body. We have called this phenomenon the *smooth muscle reaction.* In these changes, which show the preponderance of one or other side of the vegetative nervous system, we would deprecate the use of the terms, vagatonia and sympatheticotonia, as being limited and somewhat misleading and prefer the terms, *anionic,* to express the phenomena associated with vagus preponderance and increased *smooth muscle reaction* and the term, *kationic,* to express the phenomena associated with sympathetic preponderance and decreased smooth muscle reaction. We believe that the action of these kations and anions in influencing the charge of the colloids is the factor in producing change in the cell, and so alteration in metabolism which results in disease.

We would express the action of the two factors, protoplasm and energy, in the accompanying diagram (Fig. 1). This schema will show better than any description the results of our researches. It is impossible for us to reproduce here all our x ray pictures and experiments, amounting now to many hundreds, and extending over two years, but we wish here to detail sufficiently to sustain our theory in order that others may take up the study of disease from this point of view. If our contention is correct (as we believe that we have sufficient proof that it is), it is obvious that all diseases must be investigated from this point of view as it will have enormous bearing upon their treatment. We have extensively investigated mental disturbances and gynecological and surgical conditions after this method and the results are too elaborate to be detailed here, but we believe that it will have a great bearing upon the understanding and treatment of these conditions. We believe that the action of drugs and salts must be studied after this method (and we have made a number of such studies) for this is the mechanism of their action. We have found the method valuable in the study of psychic disorders as it is possible to correlate the integration of the vegetative nervous system with the mental deviations.

The metabolism in the cell changes according as the condition is kationic or anionic. In the kationic state, the cell is more permeable and the plasma diluted. A good example of this is in eclampsia where there is, in the preeclamptic state, lessened calcium, dilution of the plasma, and edema. Kationic states where edema exists may be helped, for example, by the salt free diet which lessens the intake of the kation, sodium, and so reduces the permeability of the cell. The diseases we have studied seem to arrange themselves in degrees of deviation from the kation-anion balance, but we are not prepared at present to make any classification in this regard.

We have found the various salts, sodium, potassium, magnesium and calcium, to have effect upon the kation-anion balance in that order. Sodium and potassium in certain combinations act as kations,

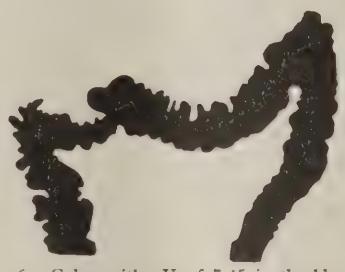

Fig. 6.—Colon with pH of 7.45 in the blood.

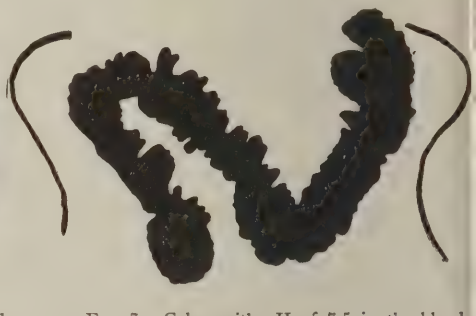

Fig. 7.—Colon with pH of 7.5 in the blood.

Fig. 5.—Colon with pH 7.4 in the blood. (According to our experience a pH of 7.4 plus, accompanies normal intestinal innervation and we would consider that the normal pH was a little upon the plus side of 7.4, but rather nearer 7.4 than 7.45) The pictures shown here have been chosen to illustrate rather wide changes in the pH for the sake of reducing the number of illustrations.

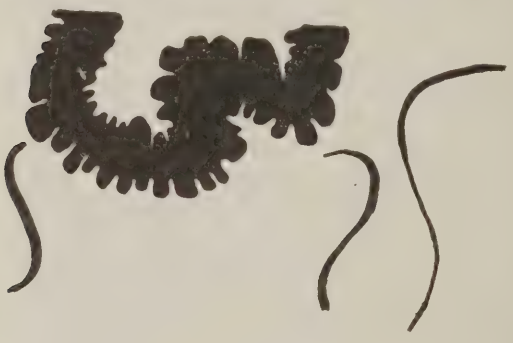

Fig. 8.—Colon with pH of 7.6 in the blood.

Fig. 9.—Colon with pH of 7.7 in the blood.

Fig. 10.—Colon with pH of 7.8 in the blood

while magnesium has a more indefinite action and most combinations of calcium, as the lactate and chloride are distinctly anionic. The acid salts, such as sodium acid phosphate, etc., seem to act as buffer salts. Sodium and potassium salts are, in general, antagonistic to calcium salts. The same criteria may be applied to the smooth muscle cells as are applied to single cell organisms in biology or to emulsions or colloids, namely that the salts of potassium, sodium, magnesium or calcium have certain effects in respect to permeability, conductivity, inhibition, potential differences, etc., depending on their electrolytic state which is affected by the hydrogen ion concentration of the fluid. In other words, certain of the salts will work in a medium of a certain degree of acidity and, as acidity changes to alkalinity, then certain other salts go into action and produce their effects. The degree of contraction or relaxation of the smooth muscle is an index of these various physiological states.

Our conclusions are that the processes of disease are the expression of the reciprocal action of the protoplasm and energy. Deviation from the proper balance, health, is marked by deviation from the kation-anion vagus-sympathetic balance of the vegetative nervous system. This deviation can be studied by the fluoroscope and recorded by radiographs of the stomach and intestines and this phenomenon is called the smooth muscle reaction.

The smooth muscle reaction varies with the hydrogen ion concentration of the blood and the kation-anion, acid-base balance. Experimental changes in the smooth muscle reaction and the vagus-sympathetic balance can be produced by the ingestion and injection of various salts. Certain diseases, as rickets, colitis and others, show a deviation from the smooth muscle reaction and the vagus-sympathetic balance. The sympathetic preponderance is called *kationic,* and the vagus preponderance is called *anionic,* because, in disease and experimentally, these

conditions go together. Disease is a deviation of the kation-anion, vagus-sympathetic, the salts and hydrogen ion balance and, inasmuch as certain diseases studied fell toward one or other side of this balance, so, all disease should be studied after this method as it may have a great bearing upon treatment.

There cannot be alteration in the body processes unless these are directed by the vagus sympathetic mechanism as this controls the heart that beats, the lungs that breathe, the intestines that move, the kidneys that secrete. . . . Disease is a deviation from normal of such body processes and is, therefore, dependent upon the vagus-sympathetic balance and this is an expression of corresponding changes in the protoplasmic cell itself. A method of the study of disease has been outlined which allows the application of biological criteria to the human organism. The smooth muscle cell follows the same principles of change and alteration in regard to viscosity, osmotic pressure, conductivity and potential differences as do the simple biological organisms used by investigators in that science.

ILLUSTRATIONS

These illustrations are made from tracings of x ray pictures over the viewing box. The pictures are taken from the front of the patient. Figs. 2 to 10 illustrate the correlation of the smooth muscle reaction with the hydrogen ion concentration, or pH values of the blood. The important thing in the study of these x ray pictures is the innervation of the colon, the form and arrangement of the haustra, that is the amplitude. These are the phenomena upon which we place importance. It is to be regretted that in still pictures we cannot show the action of the stomach and the small intestine. These are not accidents of filling the intestine, but are uniform and characteristic for each individual condition when the influence of purgatives and drugs is removed. The action of the stomach and small intestine is also of importance, but these are best studied by the fluoroscope and not in radiographs.

The hydrogen ion estimation (pH) has been done by the Hawkins method (3) as modified by Hastings and Sendroy, Jr., (4) and using the bicolor standards with pairs of tubes.

Spirochetosis Riverensis

LOUIS A. MICHELONI, M.D.
Montevideo, Uruguay

This name has been applied to a serious disease I am describing because of the circumstances and places in which I found it existing, and because of the fact that, as far as I know, this is the first description given, and since its peculiar symptomatology is not yet known to the medical world.

Taking into consideration the appearance and morphology of the organism that causes this disease it could be regarded as a transition between syphilis and Trypanosomiasis gambiensis, but the parasite that produces the disease is not a treponema nor a treponosoma but a robust spirochete larger than the Spirocheta refringens and appearing to have an undulatory membrane.

This disease has not yet been studied in Montevideo where it is being confused with syphilis. However, the Uruguayan medical men realize that a different condition of affairs exists in the north because, from time to time, I heard remarks such as, "how grave, serious and difficult to cure are those cases of syphilis in the frontier," referring to the disease I am describing which exists in the northern frontier of Uruguay, in the Department of Rivera, and in the southern part of Rio Grande, Brazil.

The disease can be safely described as a meningitis of a persistent, chronic type, which, while it does not immediately prove fatal, tends to impair the health to the extent of shortening life and ultimately producing death by the course of intercurrent diseases.

It is produced by a peculiar parasitic organism resembling the Spirocheta refringens in structure, though thicker, and showing very active movement. It is not found in the blood but it circulates freely in the watery fluid of the brain, lakes and ventricles, and probably in other structures. It may, however, be considered a disease allied to syphilis or even a manifestation of polymorphism of the organism that causes it; however, the way the human organism contracts the infection is very different.

In the majority of cases it starts with a gonorrheal infection, although it may be acquired in other ways. The gonorrheal pus does not contain the Spirocheta riverensis, but peculiar nucleated cells which probably undergo transitory variations in the lymphatic tissue before reaching the spinal cerebral fluid.

SYMPTOMS

The human organism reacts much more feebly than in syphilis and the infection is, therefore, much more severe. There is not, as a rule, the socalled rosary chain of lymphatic glands, which is the manifestation of Nature's first reaction against disease. I have seen, nevertheless, but only occasionally, in robust individuals, inflammation of one inguinal gland with tendency to suppuration. This is the exception, however, because as a rule the disease develops slowly and most insidiously as a secondary manifestation.

The most common preliminary symptoms are: general lassitude, frontal headache of neuralgic type, nervous disorders of the heart, and insomnia. In

six months to one year, the characteristic and very typical symptoms of the disease appear. They consist in disorders of vision, tinnitus aurium, and troubles affecting the heart's mechanism with more or less intensity.

EYE SYMPTOMS

These are constant and pathognomonic symptoms of the disease, so striking as to be peculiar to it. They manifest themselves with the increased irritability of the conjunctiva as the country wind will irritate and inflame the eyes of persons who, prior to infection, never suffered from eye troubles. Subsequently a mild form of iritis develops with globular pain and a sensation of fullness. A mild degree of photophobia occurs which becomes more severe, and sensitiveness to strong light may be intense. There is extreme sensitiveness to red color and to lines.

The spirochete is found visible and active in large numbers in the anterior chamber of the eye.

EAR SYMPTOMS

Tinnitus aurium is another constant symptom. It is always present with more or less intensity according to the severity of the ocular phenomenon. The sensation is that of a peculiar ringing or roaring sound in the head. I believe that this is due to the increased cranial pressure and more intense vibration of the perilymph. In advanced cases there may be extreme sensibility to sounds.

HEART SYMPTOMS

There is always an abnormal excited condition of the heart. Palpitation and tachycardia, to a greater or less extent, are always present. It is not unusual to find individuals with a permanent pulse rate of a hundred and twenty a minute.

The high blood pressure and increased hypertension may be considered as Nature's reaction to increase the circulation of the cephalorrhachidian fluid.

HEADACHE

Headache of neuralgic type, frontal lateral, or in the back, may be present in different degrees, but this is not a constant symptom. It is generally felt when awakening in the morning, usually disappearing with the increased activity in the circulation of the brain. Patients with a tendency to insomnia do not complain of headache.

After several years the preliminary symptoms gradually subside denoting a better tolerance by the human organism, and the disease, while compatible with life, becomes chronic, imperilling and shortening life. The affected individual lives in a constant state of overstimulation, has no power of resistance against disease, is debilitated, and succumbs easily to intercurrent diseases. In severe cases the tertiary manifestations develop. They consist in troubles affecting the meninges, cortex and anterior parts of the brain. I have noticed, particularly, that spinal troubles are very rare.

PECULIARITY OF EYE SYMPTOMS

The peculiarity and most striking phenomenon of this disease is that the affected individual can detect the spirochete in his own vision with the naked eye.

By looking at the sky in a gray fundus, in a sort of dreamy way, the patient can see hundreds of thousands, possibly millions, of shining bodies moving quickly before his gaze. This phenomenon is so realistic that it seems as if a cinematographic screen is placed before his eyes, or as if he were making a dark field examination with the microscope. To detect the spirochetes it is necessary, however, to adjust and train the vision accordingly. A special effort must be made to focus the pupil at a fixed and rather short distance. At first this is rather difficult, but later it becomes much easier through practice. This habit of observing the parasite soon becomes automatic, adding to the already abnormal and painful vision an increased congestion of the optic nerve.

In a room illuminated by strong sunlight the infected person can see his own spirochetes, by the proper eye accommodation, fixing his gaze on the wall, floor, or a blank piece of paper. If the paper is divided by crossed lines so as to form square centimetres, the spirochetes can be seen, whiter than the paper, moving actively, three or four of them in each square. The adult spirochetes traversing quickly a space of from two to three square centimetres are plainly visible. Reflected against the wall the size of the Spirocheta riverensis appears large, and larger if reflected against the sky, varying in proportion according to the distance, the eye acting as a magnifying glass.

The Spirocheta riverensis is more robust and highly developed than the treponema of syphilis. It is more active and its motion is not screwlike but rather eellike and it appears to have an undulating membrane. The size, as compared with the normal lymphocytes (any normal person can see lymphocytes in his own vision by the same eye accommodation) is larger than the treponema and resembles that of the Spirocheta refringens, but appears thicker. The protoplasm of this parasite is highly refractive and it has the faculty of absorbing light. Under favorable conditions, in the dark, by closing his eyes the patient can see myriads of shining bodies, namely, the spirochetes with their characteristic motion.

Another kind of microorganism constantly associated with the Spirocheta riverensis can also be seen with the naked eye. This consists of an elongated nucleated cell body moving in an elliptical and crosswise direction. The protoplasm does not appear to be refractive and, therefore, being dark, it is much more difficult to detect. It can only be seen by specially educating the eye, which causes a painful sensation in the optic nerve. The ability of detecting this associated microorganism is acquired after a few years of daily practice in looking at the spirochetes.

Whether this associated bacterium is a transitory form, a proteolithic organism or a unisexual form of the same parasite, is still to be ascertained. The lymphocytes appear greatly increased in number in this pathological condition. The spirochete appears to be astonishingly well endowed with vitality and powers of resistance. Its persistent unchecked culture in the infected organism resulting in the death of the individual is appalling.

In the zone where I detected and studied this disease, in the northern frontier of Uruguay and the southern part of the State of Rio Grande, Brazil, the inhabitants are of Brazilian origin and speak their mother tongue, Portuguese. They differ vastly from

the Uruguayan population south of Rio Negro. The infected zone is a cattle raising section where the well to do people own large tracts of land while the *peones* take care of the cattle.

My impression is that in this zone nearly the whole population is infected with Spirocheta riverensis. About seventy-five per cent. of the men I have examined have a history of gonorrhea. The chronic infection I am describing does not prevent the raising of large families, male births predominating, but the infant mortality is high and the race is poorly developed, undernourished, with little tendency to longevity.

One reason why such an amazingly large percentage of the population is infected is due to the present faulty legislation. The Uruguayan law does not protect the woman in a sufficient way, and when it does protect her the inadequate old Spanish procedure renders the law more ineffective. It was not until September 5, 1914, that investigation of paternity on illegitimate births was permitted.

CHIEF CAUSE OF SPREADING THE INFECTION

The *peona,* a girl of the poorer class, is an actual white slave, found as servant in every kitchen in the *estancias* and residences of the rich. She nearly always has been seduced in early youth and, as a rule, has several children, sometimes each child from a different father. Infected at one time or another, a servant as well as a prostitute, ignorant and without hygienic vigilance, the mistress of the *peon* (farm hand), as well as of the son of the *estanciero* (land owner), or of the *estanciero* himself, in her travels from one kitchen to another she becomes a vehicle of infection and destruction.

Young men get the infection early in life and the old habit of the patient curing himself without consulting a physician, in fact some of them do not even consider the infection worth medical advice, aids in spreading the disease. My impression is that males locally cured of gonorrhea, though with active brain symptoms of the disease, do not transmit the infection. The females, however, once infected will surely and always transmit it to their children. The infection is probably transmitted to offspring by the liquor amnii where the parasite circulates. In fact, children, as a rule, are born undeveloped, with skin eruptions and eye troubles. They frequently die young but the few who survive and recover early in life, according to conditions and resistance, are spared only to be reinfected later. In a great many cases, especially among the rich, the infection persists through life, presenting the characteristic eye, ear and heart symptoms.

The conditions regarding adults are rather different. Spontaneous cures are rare and the disease is persistent and decidedly chronic. Years of practice, observation and study in the affected zone made me familiar with the most common intercurrent diseases that ultimately end the life of the affected individual.

It is necessary to take into consideration the fact that the patient lives in a state of constant overstimulation of the natural defenses set by the human organism against the ever present living culture of the parasite in the liquid bathing the noblest and most important tissue of the body. Even in cases when the infection is well borne, ultimately life will be shortened because of the exhausted condition of resistance and general debility of the body.

In analyzing the possible origin of diseases subsequently associated with this infection, I attach great importance to troubles arising from alterations or damages in the region of the fourth ventricle, especially in the pneumogastric centres affecting the heart, the respiratory and digestive organs. Sudden deaths by heart failure, asthmatic affections, diabetes and hyperchlorhydria are very common in the affected zone.

PNEUMOGASTRIC NERVE INVOLVEMENT

The tenth pair of cranial nerves, or the pneumogastric nerve, from its origin is a motor as well as a sensory fibre and it controls and regulates the most important vital functions and nutrition. Its direct relation with the circulatory, respiratory and digestive systems is well established by the study of anatomy and physiology. Its ultimate association with the sympathetic nervous system, pulmonary, cardiac, and solar plexus which finally anastomosis at the point where it is no longer possible to differentiate the fibre endings, show how it was possible for Claude Bernard, in 1849, to produce artificial glycosuria by his famous puncture of the fourth ventricle. The pancreas directly enervated by splenic plexus receives secretory impulses from the pneumogastric.

My theory is that the diabetes mellitus, so common in the northern frontier of Uruguay, is the result of changes and alterations in the pneumogastric centres due to the deteriorating effect by permanent cultures of spirocheta in the ventricles of the brain, and also, I believe that sudden deaths, asthmatic affections, hyperchlorhydria and other secretory disturbances of the stomach, and other organs of digestion, so common there, respond to the same cause.

Troubles arising from the meninges or from the optic centres are secondary in importance. Defective intelligence and epileptic attacks in children and adults occur occasionally. Defective vision which sometimes terminates in blindness also occurs but in general the eye disturbances are not dangerous, due to the custom of the people of retiring early and saving their eyes from the use of artificial light.

The exterior appearance of the eye of a sufferer from the disease does not show abnormality. Circulative changes are, however, found by the eye specialist. The feature that impressed me most was the delicate condition of the eyes. Any trifling ailment, a light blow or knock, or other troubles will cause serious and permanent injury. This accounts for the large number of *tuertos* in the affected zone. (The name of *tuerto* is applied to an individual who has suffered total or partial loss of eyesight in one eye.)

DEBILITY AND LACK OF BODY REACTION TO DISEASE

In treating the sick one is impressed by the lack of bodily reaction to common diseases. A comparatively mild case of grippe, for instance, may become very serious. The untoward effect of drugs in some cases is extreme. A common knowledge of therapeutics may be upset and its effects doubted because of the unexpected untoward effects of drugs. Therefore, a physician must be very careful and observing when prescribing. A small dose of nux vomica or digitalis may act as an alkaloidal poison. A small

dose of morphine may produce an epileptic attack in persons who never before had had such an attack. A small dose of chloral, luminal or similar drug may produce an attack of dementia in epileptic subjects. The most alarming symptoms may follow the administration of antipyretics, especially in old persons.

CANCER

Cancer in the affected zone is extremely rare. During eight years of practice, covering a large territory, only two cases of cancer came under my observation and these two were in women. I never heard of other cases and came to the conclusion that an infection of Spirocheta riverensis may, to a certain extent, protect against cancer. The individual infected with the parasite lives in a constant state of stimulation, his power of reaction increased to the highest degree, probably sufficient to protect him against cancer, which is acquired by the old and debilitated.

IDIOSYNCRASY TO CHLOROFORM OR ETHER

A condition of exceptional idiosyncrasy in those infected with Spirochetosis riverensis is their inability to take chloroform or ether. Several persons of my acquaintance in Montevideo, operated on for gastric ulcers (hyperchlorhydria and functional disorders of the digestive organs are extremely common) died a few days after the operation. My opinion is that ether or chloroform in these persons produce considerable damage to the nerve cells and a temporary arrest of Nature's process of defense, in consequence of which the number of spirochetes in the brain increases to such an extent that death results.

SUDDEN DEATH

I have recorded several cases of sudden death in infected young persons, caused by exhaustion of the reserve power of the heart and the emotions. One young man while riding on horseback chanced to see a *tatu*. He dismounted from his horse and gave chase on foot, became fatigued, suffered pericardial pain, and died a few minutes later in a neighboring house. Another case was that of a young man out hunting who died while in the excitement of the chase. Another person succumbed when accused of murder.

POSSIBLE ORIGIN OF THE DISEASE

A rich rancher sent a young negro, about twelve years of age, to me for treatment. He admitted having had intercourse with a female dog and the result was a gonorrheal infection accompanied by an extraordinary swelling of the penis. I watched the case very carefully and a few months later I noticed that the three cardinal symptoms—eyesight disturbances, tinnitis aurium and palpitation of the heart—had developed.

WASSERMANN REACTION AND CURE WITH ANTISYPHILITIC METHODS

In the majority of cases the infected persons present a positive Wassermann reaction and are, therefore, submitted to antisyphilitic cures by the local or Montevidean physicians. In the beginning I did the same myself and tried salvarsan, mercury and bismuth, but the results I obtained forced me to drop this method with disgust, regretting the futility of such cures. I have never noticed any real good results from antisyphilitic treatment and in many instances the patient grew worse. Under the action of such treatment I have seen some improvement of the general symptoms, namely headache, insomnia, etc., but only temporarily. In no case have I ever noticed any beneficial effect on the ocular and acoustic symptoms. In many cases I have seen serious and permanent therapeutic injuries by the routine application of an antisyphilitic drug.

An acquaintance of mine in Montevideo was treated with neosalvarsan. Shortly after, spinal paralysis developed, a malady very rare in untreated cases, in fact, I have never seen an untreated patient with spinal trouble. In other subjects blindness developed and in some cases the patient became totally deaf. These afflictions become apparent after the infected persons are subjected to a series of injections. There is no doubt that many deaths have resulted from the unsuitable administration of antisyphilitic drugs.

As an exception to this I found at times that potassium iodide given in small doses had favorable results because, in my opinion, it reacted favorably against the course of the disease by alkalinizing the blood.

I have observed that in cases presenting extreme idiosyncrasy to drugs even if administered in infinitesimal doses, that—contradictory to logical effects—patients bear the disease better than those who are less susceptible to drugs. I remember the case of a young girl having a fainting spell followed by headache and a feeling of intense discomfort which lasted several days, after an absorption of surplus mercury in the amalgam of a tooth filling placed by a dentist. Imagine the result if a strong antisyphilitic drug had been administered!

SPONTANEOUS CURE

I have not the least doubt that spontaneous cures are numerous, but as a rule they occur in children and growing persons. In the adult spontaneous cure is rare and even more so in the aged. Undoubtedly the spirochetes live and die in the human organism and on their reproduction rests the life or death of the individual. The human organism offers little resistance against the fully developed spirochete which moves freely in the cerebrospinal fluid. Nature, however, seems better fitted to combat disease in the young and those in the transitory stage.

The parasite seems to possess astonishing power of resistance and, therefore, the disease is of long duration, chronic, and in the majority of cases fatal. It is interesting to observe and study the various changes in the urine of an infected person at various stages of the disease and especially in cases where there is parasitic tolerance or when the human organism shows partial immunity in a more or less degree.

A case came under my observation which I have no doubt was a spontaneous cure. One of my patients recovered from a serious attack of grippe complicated with pneumonia. He was delirious and had a very high temperature for weeks. When he recovered from these ailments he also was cured of the Spirochetosis riverensis. I believe that the continuous high temperature he had for so long in his period of illness had destroyed the parasites.

SCARCITY OF THE DISEASE IN THE SOUTHERN PART OF RIO NEGRO

This disease is not usually found in Montevideo except in visitors or persons emigrating from the northern part of the country. A fact to be taken into consideration is that the sea air proves beneficial to those affected with the disease. Patients who come to the seashore seem to obtain immediate relief and I attribute this effect to the radioactivity of the sun and sea air.

DIAGNOSIS

To diagnose the disease it is my custom to ask the following questions:

Question 1: Have you headaches or pains in the eyes? Can you stand strong sunlight? Does artificial light, red color, lines, the reflection of the sun's rays on water, glass, etc., trouble your sight? Do your eyeballs pain?

Question 2: Do you hear peculiar noises or a constant ringing in your ears?

Question 3: Have you palpitation of the heart?

I then tell the patient to look at the sky and I ask him, "Do you see any *bichitos* shining and moving?" (*bichitos* means small bugs.) To make the patient understand better what I mean when I ask if they see *bichitos* I show them the pictures of the spirochetes and lymphocytes, designed for the purpose of enabling him to differentiate the organisms.

As a rule the intelligent person answers well and is able to describe both structures. To detect the associated bacterium, described above, requires a special training of the eyes, as it is not possible to expect patients to see it at first, but the adult spirochetes are visible to every sufferer.

These questions are on cardinal symptoms and the answers are always in the affirmative when the disease is present. Other questions that follow are on the general condition of health, ability to sleep, memory, feeling of faintness, and especially on secretory gastric disturbances.

A DISEASE OF DISTINCT CLINICAL ENTITY

The disease I have described has not yet been studied in Montevideo and, as stated before, this is the first mention of it. I do not predict that this description will become classical but I am convinced that further investigation will corroborate my findings. While this is my first mention of the disease and its peculiar symptoms, laying great stress on the fact that the sufferers are able to see the parasitic organism with their own eyes, a phenomenon never before known to medical science, I will say that this article is the product of years of keen observation and thorough study pursued by me in the affected zone.

I believe in imparting this knowledge of the disease because it may lead to important conclusions in regard to syphilis and allied diseases and eventually contribute favorably to the handling of one of the most dreadful calamities of the age.

I feel proud of my American education and degree as I am conscious that this country leads the world in medical science and these facts are what prompted me to come from so far to report my work to you.

However, this paper is especially dedicated to my colleagues and countrymen of Uruguay.

I am sure that some other Uruguayan investigators better prepared and more learned than myself will take up this subject so as to be able to deal with one of the most important health problems of northern Uruguay.

Intraperitoneal Implantation of Cervical Carcinoma

New Technic for the Implantation of Cervical Carcinoma and the Extensions in the Parametria with Radium Emanation in Capillary Tubes by the Intraabdominal Route

PAUL E. DURHAM, M.D.
New York

The advantages to be gained by the procedure to be described, of opening the abdomen for the purposes of exploration and an accurate implantation of the cervical mass and broad ligaments from above with radium emanation in capillary glass tubes, are many.

At the present time it is a recognized surgical procedure to expose a neoplastic growth, that the limits of extension might be determined and that this growth with these extensions may be implanted accurately with bare tubes under guidance of the eye and the sense of touch, at the same time avoiding injury to the neighboring vital organs and structures.

Carcinoma of the uterus lends itself admirably to this method of attack, since it is difficult to determine with certainty by vaginal examination, the conditions present in a fairly extensive growth and especially if it has been previously radiated. And again, only a limited implantation can be done throughout the outermost extensions in the broad ligaments and cervical tissues effectively, when implanting by way of the vagina.

Previous to coming to the operating room, the patient is given a high colonic irrigation and a vaginal douche. Ether anesthesia is instituted and the vagina is swabbed with one half strength tincture of iodine. The abdomen is opened with a lower midline incision, the patient is placed in the Trendelenburg position and the intestines are packed back to give a clear view of the pelvic structures. Any pathological condition of prime importance is attended to but no time should be lost on minor complications. At this stage the vessels supplying the uterus are ligated. This phase will be spoken of later.

The index and middle fingers of the left hand are inserted into the vagina below and the right hand

in the pelvis above palpates against these. The operator first determines the degree of fixation of the uterus, then passes to the anterior cervical region to acquaint himself with the amount of infiltration and any involvement of the bladder present. Next the fingers below are carried laterally to the left as far as possible while the right hand above palpates

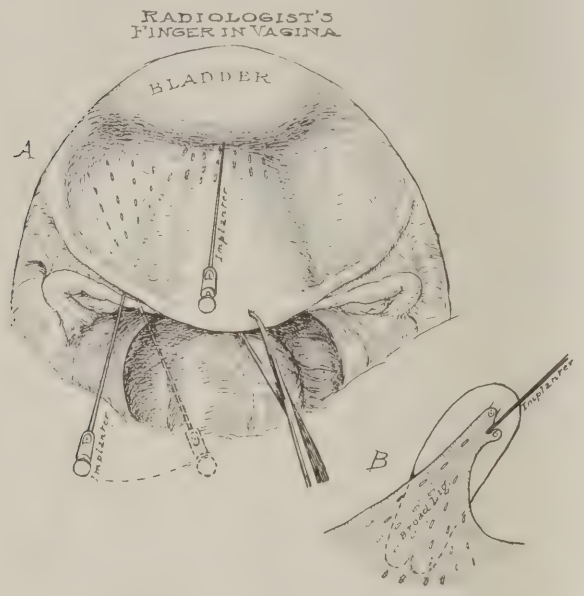

Fig. 1.—A. Implantation of the anterior cervical region and broad ligaments with the radiologist's finger in the vagina. B. Cross section of broad ligament showing the thorough implantation.

the induration of the lateral cervical region and outward extension into the broad ligament. The examination of the right side is made in the same manner. I have found it an advantage to grasp the broad ligament between the fingers and thumb of the right hand to gain further knowledge. At the same time one is able to determine the amount of destruction of cervical tissues caused by the tumor or any previous radiation. Knowing the distance of the bladder from the cervical canal is valuable to the operator since he can judge the quantity of radiation to be applied to this region, thus avoiding a vaginal fistula.

(I do not wish to consider the type of case in this paper in which the extension has passed beyond the broad ligaments.)

The uterus is retracted backward and the implanting needle is inserted in the midline passing downward into the cervix until it is felt to approach the finger in the vagina below. A bare tube is deposited and the needle withdrawn for one half to three quarters of a cm. and another capillary tube is deposited. This procedure is repeated until the requisite number is embedded in the puncture channel. Fig. 2 is a diagrammatic sketch showing a number of puncture channels approximately three quarters cm. apart with bare tubes distributed evenly throughout the involvement of the anterior cervical area. Any further involvement of the bladder wall detected by palpation or transillumination with a strong Cameron light can be implanted with a fair degree of accuracy. A supplementary implantation through the cystoscope can be performed at a later date if the extension penetrates the bladder. Dissection of the bladder from the anterior surface of the cervix gives the radiologist a better approach for the implantation of the roof of the vaginal wall, yet where it becomes necessary to traumatize the cancer tissue, it is better to implant without dissection.

For implanting the lateral cervical section and broad ligaments, especially the anterior parts of these structures, the fingers in the vagina are carried laterally while the implanting needle is inserted in the area lying between the round ligament and the tube passing downward and medially into the cervical tissue. After bare tubes are implanted in this region, the needle is angulated outward while the fingers below are carried more laterally and bare tubes are embedded throughout the extensions in the parametria especially the anterior portion.

In some cases it is necessary to make several puncture channels laterally to facilitate a thorough and even implant of seeds throughout the broad ligament to the pelvic wall. More radiation per unit volume of tissue is given to the neoplastic tissue by the embedding of more bare tubes or using seeds of higher units than is given to the adjacent uninvolved tissues of the parametria. The right side is treated similarly (Fig. 1). So far I have used from ten to eighteen capillary tubes for the implant of each side, varying the number with the degree of involvement.

In the next step, the fingers are removed from the vagina and the index finger is inserted in the rectum, while an assistant retracts the uterus forward. Palpating with the right hand above against the finger below, the operator determines the degree of involvement of the post cervical region. By carrying the examination laterally, the infiltration in the posterior section of the broad ligaments is noted. After bare tubes are implanted in the posterior section of the cervix the implant needle is next inserted in the cul de sac passing downward and forward until felt to approach the finger in the rectum. By the sense of touch and the exercise of care, bare tubes may be implanted within a short range of the rectal wall if necessary without puncture or injury. From three to five puncture channels are ordinarily

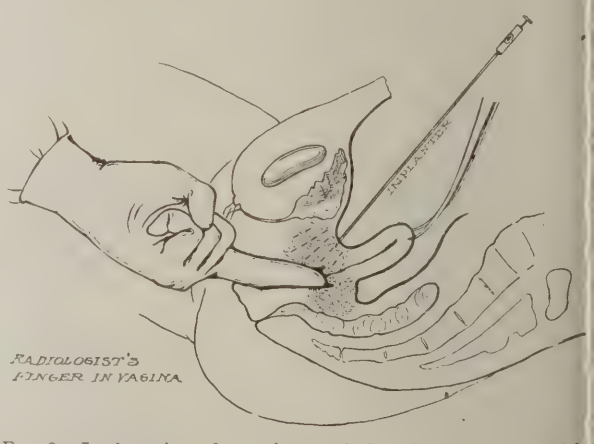

Fig. 2.—Implantation of anterior cervical region with the radiologist's finger in the vagina.

essential for accomplishing this procedure (Fig. 3).

Succeeding this, the finger below is carried laterally and the posterior sections of the broad ligaments of the left side are implanted—something which was not able to be accomplished so successfully while the finger was in the vagina. This technic is applied to

the right side also (Fig. 4). If ligation of the vessels was previously resorted to, the peritoneal openings are not closed until after the implantation is completed. Readier access to the involved area is afforded since the implant needle is inserted through these openings without injury to the ureters and large

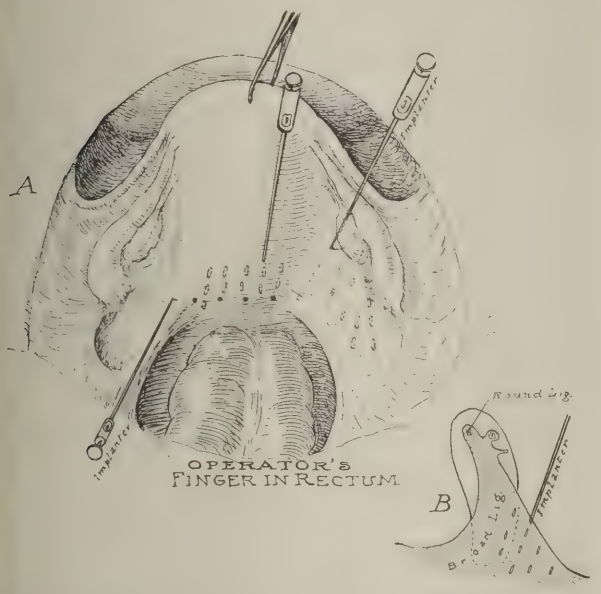

Fig. 4.—A. Implantation of posterior cervical and parametrial tissues. B. Method of implanting posterior section of the parametria.

vessels whose position is clearly defined (exposed).

A cigarette drain should be left in the culdesac extending from the lower angle of the wound if there is fear of infection following. Cancer tissue has been proved to harbor infection in some cases, and the necessary amount of emanation used stimulates the production of a serous exudate. Considering these facts, it would appear that a drainage is warranted. But in a recent case where the drainage was omitted, the patient made a rapid recovery.

Provided the involvement of the parametria is not too extensive, a bilateral catheterization of the ureters will aid the radiologist in avoiding injury to these structures, especially when the vessels are to be ligated. The ureters are somewhat more resistant to radiation than most other structures which permits us to implant bare tubes in close proximity to them without apparent harm.

LIGATION OF UTERINE ARTERIES

Ligation of the uterine blood supply is essential. This ligation may be a combination of any of the arteries which supply the uterus, i. e., the anterior branches of the internal iliacs, the uterine and ovarian arteries. I believe that the ovarian arteries should be ligated in all cases, together with the anterior branches of both iliacs. It is more efficacious in the less extensive cases to follow Dr. T. H. Morgan's technic of substituting the ligation of the uterine for the iliac on the side preferred. These vessels above should be ligated as near to their source as practicable.

As stated above, this not only controls the immediate hemorrhage, affords readier access to the implantation of the involved area, lowers the resistance of the cancer cells to the radiation, but decreases the nourishment to the tumor and acts as a safeguard to future hemorrhages should the radiation produce any necrosis. But the amount of radiation must be decreased if the vessels are ligated.

Suffice it to say, that one should attempt to clear up any pelvic infection before proceeding with the technic outlined above and all care should be used to avoid embedding bare tubes in infected tissues.

Involvements of the vaginal walls are best treated by applying filtered radiation to the surface by the vaginal route.

When the patient's condition permits, it is my opinion that the intraperitoneal implantation with a ligation of the uterine blood supply should be performed primarily. This method is especially advantageous since the operator does not have to face the difficulty of determining whether the induration of the parametria is a carcinomatous infiltrate or one of fibrosis produced by any previous radiation. The furthermost extensions are immediately checked and the hemorrhage is controlled.

METHOD OF APPLYING RADIATION

But when the patient's condition is poor and a laparotomy is too hazardous, the usual method of treatment is resorted to, namely, the insertion of uterine metal tubes in tandem containing radium in such a manner that the cervix receives approximately double the amount of radiation as does the fundus. In addition to this, it will often prove beneficial to implant bare tubes in the cervical mass and parametria laterally to a limited degree through the vagina. By taking this step, the hemorrhage is checked, the cancer cells are rendered less active and the foul smelling cervical mass, if present, is removed. This permits the patient's condition to improve to such an extent that an intraabdominal implantation is made possible later. If, however, there is any destruction of the cervical lips, then the dose must be decreased in proportion to the degree of destruction, because of the danger of inducing a slough.

Several factors, more or less variable, need to be considered according to the case in hand. Some of

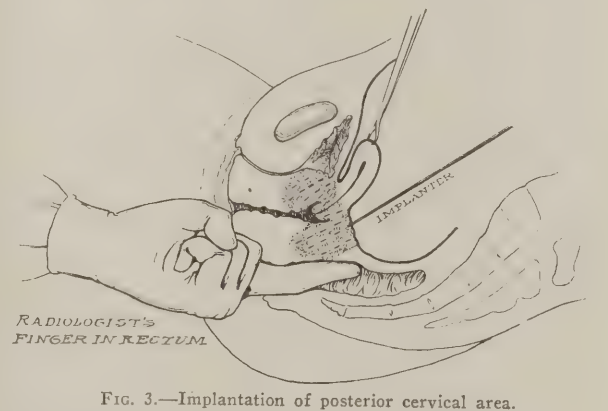

Fig. 3.—Implantation of posterior cervical area.

the leading radiologists at the present time recommend bare tubes of approximately one millicurie for the treatment of neoplasms in other regions of the body. But from recent experience, I believe the best results are obtained when bare tubes of lower units are used in this work, ranging from two tenths

to six tenths millicuries. If capillary tubes of lower concentrations are used, then the operator is permitted to use a greater number which facilitates a more even distribution throughout the neoplasm. While if bare tubes of the higher units are used, the effect is escharotic in nature, and the necrosis which takes place will often be followed by fistula, hemorrhage, infection and severe pain. It has been referred to above that a greater number of bare tubes of higher units are embedded per unit volume of neoplastic tissue than are in the uninvolved adjacent to the growth. If in the former, bare tubes of three tenths millicuries are used, this affords approximately forty-four millicurie hours while for the latter four tenths gives off thirty-three millicurie hours of unfiltered beta radiation (as well as gamma). I have used in the neighborhood of twenty millicuries in sixty or more bare tubes without sequelæ in nonradiated cervical carcinoma and parametria with ligation of the blood supply.

RESULTS OF TREATMENT

The chief object in applying radiation in such doses as mentioned above is to bring about a gradual change in the neoplastic cells so that they are devitalized *in situ*. At the same time the radiation inflammation in the adjacent uninvolved tissues of the parametria stimulates the production of fibrous tissue and blocks the lymphatics which prevents further extensions and metastasis. While I was on the service of Memorial Hospital, Dr. D. Quick stressed the importance of distributing bare tubes in the periphery of the tumor. But from recent experience, I believe better results are obtained not only in following this procedure, but by implanting even beyond the base of the tumor in the adjacent surrounding tissues. This step, in addition to the effects mentioned above, produces changes in the walls of the arterioles and the abundant uterine venous plexus thereby diminishing the supply of nourishment to the tumor. The ultimate effect, then, is a radical complete radiation hysterectomy without an accompanying high rate of mortality.

Schmidtz recognized the incompleteness of controlling cervical neoplasms by the insertion of uterine metal tubes of radium alone, in those growths which had extended beyond the cervical tissue, when he stated, "A limitation to the application of radium is given by the bladder anteriorly and by the rectum posteriorly. The mucosa of each is two cm. to three cm. distant from the cervical canal, the seat of the radium tube in uterine applications."

And elsewhere Schmidtz stated, "As most pelvic cancers have invaded the regional lymph nodes, usually six centimetres distant from the cervical canal, all cancer cells cannot be reached with radium without irreparable injuries to normal tissues."

Recently, in a case of inoperable cancer, Schwartz introduced radium needles into the abdomen through a laparotomy incision.

Proust and Mallet used radium tubes holding about two milligrams of radium element which are protected by a filter.

In a recent conversation with Dr. Benson, he stated that he followed the intraperitoneal method of implanting uterine carcinoma in certain cases.

I am unable to find any description of the method described in literature whereby the radium emanation bare tubes are implanted in the uterine carcinoma and broad ligaments intraperitoneally.

CONCLUSIONS

The abdominal route for the implantation of bare tubes of radium emanation into the cervical carcinoma is not applicable in those cases which: 1. Refuse laparotomy. 2. Are amenable to surgical eradication. 3. Have metastasis and extensions beyond the parametria.

But it is the most preferable method of treatment in the following conditions:

1. In those cases where the extension has passed to the parametria.
2. In the borderland type of cases where the surgeon is doubtful of being able to remove all the neoplastic tissue completely.
3. When the patient will permit a laparotomy for the purpose of implantation but not for radical hysterectomy.
4. In cases where the patients have been previously irradiated by the vaginal route in whom surgery is not practicable but who have recovered sufficiently to undergo a laparotomy.

ADVANTAGES OF TECHNIC DESCRIBED

Some of the advantages offered by the technic described are:

1. It is the only means of application of sufficient radiation to destroy all neoplastic tissue in a very large percentage of cases without severe injury to the bladder and rectum.
2. It is not accompanied by a high rate of mortality.
3. The lymphatics are blocked and many of the venous radicles are closed.
4. The nourishment to the tumor is decreased.
5. Hemorrhages are controlled by the ligation and radiation.
6. Laparotomy is essential for, a, determination of the degree of extension; b, ligation of the uterine blood supply; c, and an accurate distribution of the radium emanation tubes evenly throughout the neoplasm under guidance of the eye and the sense of touch without injury to the bladder and rectum.
7. The cancer cells are devitalized *in situ* without favoring metastasis and extension.
8. The fibrosis produced in the adjacent uninvolved tissues acts as a barrier to an extension where any cells become active at a later date.
9. A supplementary application of radiation may be given by the vaginal route later, if necessary.

Psychology, Psychopathology and Psychotherapy in Tuberculosis in Civilian and Military Life

S. ADOLPHUS KNOPF, M.D.

New York

A lengthy paper on this subject was prepared upon the invitation of the editor of *The Military Surgeon.* It was read in part by the author before the annual meeting of the Medical Association of the Greater City of New York at the New York Academy of Medicine on January 19, 1925, and appeared in full in the March number of *The Military Surgeon,* which is the official publication of the Association of Military Surgeons of the United States. Although the journal is widely read by the members of that organization, few physicians in civil life have an opportunity to read it.

The subject matter dealt with in this article, however, is equally important for military and civilian physicians, so I am glad to avail myself of the hospitality of the MEDICAL JOURNAL AND RECORD to reproduce the article in a condensed form, giving what is most essential to both civil and military practice.

I had been prompted to write this paper because of two recent articles, one by Dr. George A. Crofton, entitled The Mental Phase of Tuberculosis, which appeared last June in *The Military Surgeon,* and the other entitled Neuropsychiatry in Tuberculosis, by B. J. Weigel, of the Albuquerque Sanatorium, New Mexico, which appeared in the MEDICAL JOURNAL AND RECORD of January 7, 1925. In these articles the mental status of the tuberculous is pictured in a manner which I consider not based on facts and experience but as most unfair and unjust to the consumptive sufferer.

I quote from Dr. Crofton's article: "In general, the mental reactions of the phthisical patient may be said to indicate a reversion to childishness. Such suppression and modification of original tendencies as may have resulted from environment and education are to a large extent broken down by the disease, and the weakened physical condition of the consumptive affords them an opportunity to appear boldly and unhindered. In other words, the patient has a tendency to react in a primitive, instinctive manner, acting upon impulse, driven by his unbridled emotions, at the mercy of his own undisciplined will."

Dr. Weigel makes the following statement: "The necessary restraint and careful living imposed upon the tuberculous in all stages no doubt tend to bring about a chronic invalid reaction which borders on, if not actually constitutes, a neurosis." He says that among two hundred patients he had studied carefully, ninety-four were suffering from a definite psychoneurosis or psychosis.

These strong statements remind me of a controversy I had, some years ago, over an article which appeared in the *New York Medical Journal,* written by Dr. G. A. De Santos Saxe, and entitled Psychical Relations of Tuberculosis in Fact and Fiction. Quoting another author who had found a number of patients disregarding his orders concerning the care of their expectoration, and observing one who had expressed the wish that his young wife should not survive him, Dr. Saxe made the following statement: "To me this account shows the germination of a homicidal tendency, which is the resultant of the psychical defects that I have outlined in my analysis of the average consumptive's mental peculiarities. Here psychasthenia, the loss of self-control, and the rise of brute selfishness have combined to distort the clearness of ethical perception. . . . The fundamental factors in the psychical makeup of the typical consumptive are the loss of selfcontrol, the rise of brute selfishness, the increase of susceptibility to suggestion, to emotion and to nervous irritation, and the tendency to rapid nervous and psychical fatigue."

In a recent otherwise very excellent textbook on tuberculosis by Dr. Fishberg, we read a similar statement: "A psychic trait of the consumptive which has been noted by most writers is selfishness. He becomes egotistical and egocentric, he is interested in the welfare of but one person—himself—to the exclusion of all who have depended on him before. He will eat costly food while his children starve; he will make unreasonable demands on his relatives and friends and show no gratitude. As Saxe states, the ascendency of selfishness plays the most important rôle in the molding of the mental traits of the tuberculous."

I protested against these accusations at the time and collected the opinions of some of our leading men to back me up in my plea for fair play and justice to the consumptive. For this occasion I will quote only a few of these opinions. Hermann M. Biggs wrote: "I do not believe that there is any greater evidence of selfishness, loss of selfcontrol, or distortion of ethical perception in the consumptive than in other persons." Edward G. Janeway said: "It is my experience that the average consumptive is not inclined to brute selfishness, loss of selfcontrol, and hence distortion of the clearness of ethical perception. I have found so much to the contrary that I am surprised at so broad a charge against the consumptive invalid." Our unforgettable Sir William Osler wrote: "My impression is that the unfortunate victims of tuberculosis are above the average in their mental and moral character; secondly, I should say emphatically that the average consumptive is neither inclined to brute selfishness nor any special distortion of the ethical perceptions. Such statements as made in the *New York Medical Journal* are an unwarranted slander."

Two eminent experts versed in our most modern conception of psychopathology, when asked to express an opinion on the supposed mental abnormalities of the average consumptive, had this to say: Carlos F. MacDonald: "A large experience in the care of insane consumptives, together with the observation of at least several hundred cases of tuberculosis who were not insane, makes me agree abso-

lutely with your own views as to the moral qualities of the average consumptive. My noninsane patients, almost without exception, exhibit the cheerful, hopeful mental attitude that is common in tuberculosis."

Gregory Stragnell, editor of the Medical Journal and Record: "From my experience, the psyche of the patient with a tuberculous lesion is no different than that of a socalled normal person. Among them we find psychoneurotics and psychotics but we cannot generalize as to the psyche of a large number of persons afflicted with an organic condition, such as tuberculosis. Undoubtedly the psychological factors play an important rôle in the picture as a whole. It would be well worth while to conduct an extensive study to ascertain the interrelationship between the psychological factors and the organic condition. This would apply of course to every organic situation. This would be of service in both the prophylactic and the therapeutic fields. Specialists in tuberculosis are cognizant of this fact, quite unconsciously no doubt. This is shown by the attempt to place the tuberculous patient in as cheerful and wholesome environment as possible. The psychological background should be considered as important as the other components of diet and fresh air. There is much to be done in working out the finer details of these interrelationships, and Dr. O'Malley, of Washington, D. C., and Dr. Smith Ely Jelliffe, of New York, have gone into this matter, and it would be well to give an impetus to the work they have begun."

Of my own experience, gathered from a thirty years' exclusive practice among the tuberculous in all kinds of environments and in all stages of the disease, I may say that among the dearest recollections of my life I will always count the gratitude of many consumptive patients, expressed either at the assurance of their recovery or for the care bestowed upon them when their case was beyond human help. I could mention many instances where a well to do tuberculous sufferer provided munificently in his will for the care of the consumptive poor. Does this indicate a reversion to childishness or an undisciplined will, a psychosis, or a psychoneurosis?

What shall I say of the many physicians who engaged in tuberculosis practice because they had had the disease themselves and became eminent in their chosen specialty? The first one that comes to my mind is of course that saintly figure, Edward Livingston Trudeau. You all know his life. Now listen to the reply he sent me when I asked his opinion on Saxe's statement: "I have seen certainly more patience, courage, selfdenial and unselfish devotion to others in consumptives than I have noticed in the majority of healthy human beings. Indeed, the sanatorium work never could have been carried on were it not for the selfsacrificing devotion to the suffering of others shown by my associates, the nurses, and even the employees at the sanatorium, most of them having come here originally because suffering from tuberculous disease. History is full of instances which prove that tuberculosis does not interfere with the development of the highest degree of the intellectual, the moral and the ethical sides of man's nature."

My two European teachers, Professor Grancher of Paris and Geheimrat Dettweiler of Falkenstein, were both tuberculous; they not only accomplished great things, but they could also enthuse their pupils by their own keenness, their analytical minds, and their strength of character. As an example of the latter quality, I must mention my English friend, Sir St. Clair Thomson, who, with his high intelligence, great force of mind and strong character, succeeded in curing himself of a serious laryngeal tuberculosis with pulmonary involvement by imposing upon himself one year of absolute silence.

There are many among the leaders and officers of the American National Tuberculosis Association and among the physicians in tuberculosis sanatoria and health resorts who have been, or are still, actively afflicted with tuberculosis and who nevertheless have done or are doing splendid work, and in whose daily beneficent labors not the slightest trace of a mental peculiarity could be discovered. There are too many to mention them all, but a few of them may be cited.

Colonel George E. Bushnell, of the United States Army, who passed away only recently, was the head of the antituberculosis work during the World War and did yeoman service in this capacity. Herbert M. King, the genial medical director of the Loomis Sanatorium, left a splendid heritage of ideal sanatorium work. McDugal McLean left as his last gift to his fellow sufferers that wonderful and inspiring little volume *Tuberculosis, A Primer and Philosophy for Patients and Public*. Among those still in the midst of an active life are Edward R. Baldwin, dean of the Trudeau School; Lawrason Brown, his equally eminent associate; David R. Lyman, Charles L. Minor, and Gerald B. Webb, all acknowledged as great authorities in tuberculosis and expresidents of the National Tuberculosis Association. Our most distinguished American writer on nearly all phases of pulmonary tuberculosis, Allen K. Krause, the editor of the *American Review of Tuberculosis*, is another glorious example of what a tuberculous invalid may accomplish.

Edward S. McSweeny who, from personal experience as director for many years of the Municipal Sanatorium at Otisville and later as superintendent of the Sea View Hospital on Staten Island, can certainly speak with authority on the subject, expresses himself as follows:

"Most of the observations on which have been built the theory of the psychology of the tuberculous date back to the opinions of people who did not have the opportunity to study large groups for a long time, and, like many other observations of like character, can be relegated to the interesting domain of medical curiosity. Tuberculosis is not the cause of the objectionable characteristics which distinguish some of its victims, as has been wrongly and superficially thought and said by those who have failed to recognize that it, like disease in general, especially chronic diseases, was a powerful mordant to bring to light the individual's true character. Despite the belief which has found lodgment in many minds, my conviction from years of dealing with consumptives is that they are a long suffering, patient, normal group."

In thus defending the tuberculous sufferers at large against the stigma of being afflicted with any psychoneurosis or psychosis, I would of course not wish to deny that there may not be among a number of tuberculous invalids some who have inherited or acquired a peculiar nervous or psychological condi-

tion which deserves to be called pathological. They are the exception, however, and not the rule and such conditions may be found in chronic invalidism of any kind.

Prior to a definite diagnosis, the tuberculous patient sometimes likes to lull himself into the belief that there is nothing serious the matter with him in spite of distinct symptoms, and he is afraid to seek medical counsel for fear of a definite diagnosis. If a diagnosis is made on physical signs only, he may still be doubtful because the bacilli are not yet found. Since the x rays show old healed lesions as well as the active ones, he will probably comfort himself with the thought that his lesion is not active and that he had heard of many people going about with latent lesions and being considered healthy individuals. This desire to postpone the knowledge of a definite diagnosis must be dealt with in a most tactful manner. As a result of the definite diagnosis the patient may become hopeful, despondent or indifferent; it will depend on his temperament, his social and financial condition. The situation may be complicated by prospective marriage, and in the woman by the desire for motherhood. Here the tuberculosis specialist must become the skilled psychoanalyst. In terminal cases, when the tuberculin, constantly created, produces a veritable anesthesia, the patient often becomes optimistic and sure of his recovery. It goes without saying that to undeceive him in this happy state of mind would be useless, unwise and even cruel. What must be guarded against in such a condition is for the patient to attempt to make any extraordinary physical effort which he was unable to do a little while before. If this is not impressed upon him, some overexertion may hasten a fatal issue by a heart strain or severe hemorrhage. Nevertheless, this state should be utilized to urge the patient to put his house in order and he may be reminded that no one has ever died from making his will.

To prevent the possible development of a psychosis or psychoneurosis in a tuberculous patient, the physician should receive him in a cheerful, well ventilated room, scrupulously clean, and with fresh reading matter on the table. If at all possible, tuberculous patients should be received by special appointment. A reception room full of coughing patients, some not over careful when coughing, spraying the air with infectious droplets, may be enough to lay the foundation for a psychosis. In the anamnesis not too much stress should be laid on family history, but emphasis should be laid on the fact that the loss of one near relative by tuberculosis does not mean that the rest of the family is doomed. The patient should be told that if a hemoptysis has occurred or will occur, it is one of the phases of the disease which by no means lessens the chances of recovery. Concerning the sputum, he should be assured that if he takes care of it there is not the slightest danger of his giving the disease to anybody else, and his relatives and friends who may be with him should be warned against developing phthisiophobia. Nothing will make the tuberculous patient more miserable and despondent than to be treated like a leper.

The prognosis should always be guarded but expressed in hopeful terms, and no fixed time for recovery should be set. The patient should be impressed with the fact that the more carefully he carries out his instructions the sooner he may look for the arrest of the disease.

The patient should be asked directly if he has any mental anxiety, and if it is within the power of the physician to remove it, he should endeavor to do so. If he worries on account of financial matters, the relatives should be informed of it so that steps for relief may be taken. The patient who worries will not eat well, and his recovery will be inevitably retarded thereby. Worry and anxiety are among the greatest obstacles to the successful treatment of tuberculosis, particularly among the poor, when the patient is the breadwinner of the family. Doomed to temporary inactivity, as otherwise he cannot be restored to health, he usually broods over his fate and worries about how those who are dependent upon him will get along. As already suggested, wherever the relatives are in a position to relieve the patient of financial worry, they should strive to do so, but when the relatives themselves are poor, of course no relief can be expected from them. The wonderful results obtained by Dr. Pratt, of Boston, were doubtless due to the fact that with the aid of funds placed at his disposal by the Emmanuel Church he was enabled not only to take the very best of care of a large number of his tuberculous poor by installing the sanatorium treatment in their own homes, but he could investigate the financial resources of all the patients under his care, and when there was want, the good men and women of the church supplied food, clothing, and other necessities of life for the family so that the patient could feel absolutely sure that those who were dependent upon him were amply provided for. To appreciate this phase of psychology in the treatment of the consumptive, one must have observed the psychological change in a patient who was suddenly relieved from anxiety concerning his loved ones by the assurance that all was well at home and that there was no suffering or want. It is not to be wondered at that the results obtained by Dr. Pratt equalled, and in some instances surpassed, the best results obtained in sanatoria for the consumptive poor located in almost ideal climatic regions. Here is a field where public and private philanthropy can do immeasurable good.

Good but not exciting books and quiet and hopeful conversation will help to pass the time pleasantly and lead the invalid's thoughts away from his disease. The controlled diaphragmatic breathing, which may also be called rest breathing, aside of its beneficial physical effects, has proved to be of great value in diverting the patient's mind from his troubles, as it requires concentration. It is a good idea to tell him that whenever he feels depression coming over him he should immediately resort to this therapeutic measure, and he should be impressed with the thought that every time he saves his lungs an unnecessary movement he produces local rest for an inflamed organ which hastens his cure, and also quiets his usually rapid heart action.[1]

In institutions the patients should be forbidden to relate their trouble one to another or give advice to do this or that. The patient should receive only such visitors as he desires to see and they should be

[1]To any physician interested in this method of controlled diaphragmatic breathing Dr. Knopf will be very glad to send a reprint explaining in full the modus operandi of this method and giving the reports and opinions of leading authorities on the subject.

asked to talk as little as possible of the patient's ailment. Persons inclined to melancholy, or those who are apt to irritate the patient, should be asked to shorten their visits and appear as seldom as possible.

The desire to try quack remedies is sometimes not confined to the ignorant alone. The pamphlets issued by the American Medical Association and the National Tuberculosis Association on *Quacks and Quackeries* are often good literature to hand out. If the patient desires a climatic change, having heard that in this or that climate someone was cured, it may often be just as well to let him have his way. Insomnia, due to pure overactivity of mind or to too much introspection, is nothing unusual in the tuberculous, and since opiates and bromides should be avoided as far as possible, the method of diaphragmatic respiration will prove an excellent means to produce the complete relaxation of mind and body most conducive to sleep. With a little practice he will soon learn to control his cough, and only cough when he has to expectorate.

In the actively tuberculous invalid one quite often finds a disinclination to taking food, or a sufficient amount of food. This type of anorexia is rarely based on evident gastric or intestinal disturbances but may be considered exclusively nervous or psychic. Such patients must be taught that their capacity for digesting and assimilating is far greater than their appetite may indicate, and if they can overcome their disinclination and eat regularly and sufficiently, they will improve rapidly.

Some patients will bear pain patiently, others will magnify it. The physician should listen sympathetically to complaints even if inwardly convinced that the trouble is imaginary or greatly exaggerated in the patient's recital. Nothing is gained by disputing the patient's claim that he suffers, but he may be told that the trouble is probably of nervous origin and will pass away as soon as he is quiet. If the patient is actually suffering he should, of course, be given relief by medicinal agents. If his mind is depressed and it can be diverted to other things by rest breathing, autosuggestion, work, or prayer, the medical attendant will of course resort to these means. If the patient is of a religious nature, the cooperation of the minister of his church is often most helpful to overcome despondency and restore a hopeful outlook to the discouraged sufferer.

It may often be of great advantage to the tuberculosis specialist to familiarize himself with our newer conception of neuropsychiatry so as to be able to suggest wisely, persuade, and reeducate. Besides this, there are some qualities of mind and character which the tuberculosis physician must cultivate in order to meet all the psychological conditions which may arise in the tuberculous invalid. There is needed first of all, an unbounded enthusiasm for his work and a firm belief in the preventability and curability of tuberculosis. He will need a never failing cheerfulness and kindliness, patience and gentleness, and an absolute firmness when firmness is necessary. Imbued with his divine mission as a healer of an infirm body, which is often the cloak of a sick and weary soul, he will rarely fail to give the tuberculous patient the hope and cheer which is so essential to recovery and comfort and peace where human aid cannot avail.

Occupation therapy, now so extensively applied for rehabilitation of our war veterans, and also in some civilian tuberculosis institutions, is of inestimable value in psychotherapy. When the occupation can be made remunerative, it is so much the better. Of course, the patient must not be allowed to overwork in order to earn more. The new factory recently established here by the New York Jewish Tuberculosis Committee, where the patient's earnings are supplemented by a fund so that the tuberculous invalid can feel that with his earnings added, he is again supporting his family, is an institution well worth emulating. It means raising the morale and selfrespect of the patient and prevents mental depression.

All that has been said thus far of the tuberculous invalid in civil life is also applicable to the tuberculous soldier and exsoldier, yet the physician who has to deal with the latter class must admit that a peculiar psychology may be at times observed in military life. The physicians who have had occasion to serve on draft boards as well as the officers in active service whose task it is to examine volunteers for admission in the army, will know that the man who is eager to enter military service will hide any possible infirmity, and when asked the usual questions pertinent to the anamnesis of tuberculosis, he will flatly deny ever having coughed or spit blood, having had a real hemorrhage, fever, or continued loss of weight, or experienced any feeling of tiredness, etc., and no family history of tuberculosis will be admitted. On the other hand, physicians on draft boards will recall instances where an individual in apparently good health but eager to escape military duty, gave a perfect tuberculosis family history and recounted on examination all the symptoms of tuberculosis. He would give a clinical picture of a typical tuberculous patient with accuracy and his answers would resemble those of a third or fourth year medical student. A careful physical, x ray, and sputum examination and a few days' observation will of course clear up such cases.

Tuberculous exsoldiers are sometimes difficult to handle, because, being no longer under military orders, they do not like the new discipline. A heart to heart talk by the ward surgeon usually suffices to convince the invalid that without discipline he can not get well. The nostalgia, which becomes very pronounced with some of the exsoldiers when they have been away from their homes and families for a long time, is apt to increase with the enforced bodily inactivity and sojourn in the hospital. This, the present administration of the United States Veterans Bureau, under the leadership of General Hines, is trying to overcome. A number of War Veterans Hospitals for tuberculosis have been established in various states from the Atlantic to the Pacific so that the tuberculous exsoldier may be in an environment as near as possible to his former home.

Occasionally, there is one regrettable phase met with that is distinct and unique in the tuberculous exsoldier. Our generous government has provided him with a handsome pension besides his being housed, well fed, and well taken care of in general, in our fine new war veterans hospitals or in a pleasant boarding house in some health resort. He rather enjoys the inactive life and has no desire for the change which would come about by an arrest or cure

of his disease, cutting off his pension and forcing him to leave the hospital. Such patients will do everything possible to prolong their stay, even going so far as to procure or purchase tuberculous sputum to make the examiners believe that they are still in the active stage of the disease. Such a patient must be treated with firmness and convinced that he will enjoy life more as a recovered selfsupporting citizen than to remain a chronic invalid.

It was my privilege to serve for nearly two years as physician to tuberculous veterans of the recent war, and while I must admit that there were occasionally among my patients some of the types just described which were hard to discipline, some inclined to alcoholism and even drug addiction, because the unscrupulous drug and alcohol venders found the hospital comparatively easy of access, as a whole I look back upon my service at the United States Veterans Bureau Hospital No. 61, at Fox Hills, Staten Island, with the most pleasant recollection and with the firm conviction that even among the war veterans it cannot be said that there is any distinct psychosis or mental phase due to pulmonary tuberculosis alone.

In the many years of my labor among the tuberculous I have never seen more courage, more patience, more helpfulness and genuine sympathy for each other, and at the same time more cheerfulness, than among the tuberculous exservice men and women at the United States War Veterans Hospital No. 61. On the battlefields of Flanders and France, on land and on sea, when they were facing death or shot and shell, they sang "Smile, smile, smile," and they are still smiling today.

In conclusion, I desire to protest with all the vehemence possible, against the accusation that the million tuberculous still in the midst of our civil population have reverted to childishness, are driven by unbridled emotions, are egotistical, egocentric, and ungrateful, and that nearly fifty per cent. of them are definitely suffering from psychoneurosis or psychosis. With equal ardor would I defend against these characteristics the more than ten thousand American soldiers who returned to us tuberculous from the World War, and those who were not able to return because too severely wounded by the deadly bacillus and who finally made the supreme sacrifice.

Simplified Device for Chest Aspiration

MILTON A. BRIDGES, M.D.

New York

This little apparatus for chest aspiration is readily portable and inexpensive. It has been successfully used for the past three years in both private and hospital practice. In comparison with some of the aspirators now in use, it offers a minimum chance for air leakage and production of artificial pneumothorax. With it asepsis is easily maintained and clogging of the aspirating needle or valve can be overcome without difficulty. The parts of the instrument require very little care and will not deteriorate.

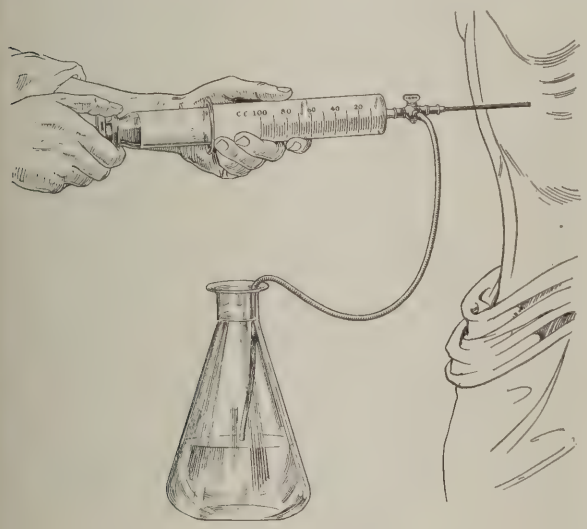

Fig. 1.—Syringe

The following illustration and directions speak for themselves:

Parts.—One hundred c. c. Luer syringe. Rubber tubing three eighths inches diameter, twelve inches in length. Three assorted gauge needles adapted for Luer nozzle. One special B-D Luer fitting stopcock.

Directions.—Stopcock is interposed between the needle and the syringe. The rubber tubing is connected with the side outlet of the stopcock. The turn key is set pointing toward patient. After cocainization of the parts, the needle, attached as above, is inserted between the ribs. Withdrawal of the plunger draws fluid from the pleural cavity. The average hundred c. c. syringe will readily hold 130 c. c. with each withdrawal of the plunger.

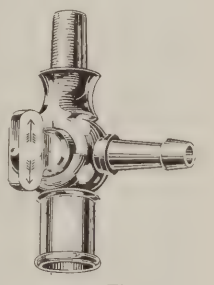

Fig. 2.—Three way stopcock.

After the syringe is filled, the three way stopcock is turned, the plunger pushed in and the fluid emptied through the rubber tubing into a waiting container. This process is repeated until the desired amount of fluid is removed.

In the event of plugging by fibrin, pus, or other material, withdrawal of a few c. c. of sterile water or saline from a container back through the rubber tube into the syringe and subsequent clearing of the needle will readily remove any such material from the apparatus.

148 West Seventy-fourth Street.

The Diagnosis of Acute Conditions of the Brain

J. VICTOR HABERMAN, M.D.,
New York

(*Concluded from page 542*)

SYPHILIS

When we approach the subject of syphilis we open up a mercilessly difficult chapter. One must keep in mind a bird's eye view of the neuropathological possibilities. Syphilis may be latent (XXXVI) or active. Where active, whether acquired or congenital, one may get a meningitis or encephalitis—most usually a meningoencephalitis, gummatous massing, in circumscribed areas (tumorlike) or diffusely spread out (especially basal). The vessels in the affected parts become implicated, and there may be breaking of same and softening of areas. One may furthermore get cerebral endarteritis (Heubner), with occlusions, aneurysms or miliary aneurysms and hemorrhages, a serous meningitis, paresis. These conditions are chronic. The patient may have outspoken symptoms of these various forms, or only mild manifestations —so mild as not to be noticed, or nothing but residual stigmata of earlier outbreaks, or, as is often enough the case in congenital syphilis, no manifestations at all (96). But any of these forms may show acute exacerbations. Thus, in a person who knows he has syphilis, or in one who doesn't suspect it, "out of a clear sky," so to speak, brain symptoms may appear: headache, dizziness, convulsions, coma, hemiplegia or monoplegia, aphasia, cranial nerve paralyses, hemianopsia, blindness. Usually there is no temperature, yet occasionally there may be. In the arterial form, one will have disturbance in circulation and nutrition and productive inflammation of tissue, with secondary sclerosis, and so, often, mental or character changes.

An acute syphilitic meningitis, though unusual, also occurs, clinically serious and often almost identical with the picture of tuberculous meningitis. This is likewise true of the occasionally acute gummatous form. There are the same prodromata in both, acute hemiplegia or paraplegia, convulsions, delirium. In both cases, also, there may be a lymphocytosis and a positive Phase I [Nonne]. Syphilitic meningitis serosa may also suddenly flare up and become serious. Perhaps a syphilotoxic encephalitis may also occur on the basis of lues—as Oppenheim surmised. This author deemed a nongummatous simple meningitis possible though this was doubted by Virchow and Heubner.

With the exception of paresis, the symptoms occasioned by these various pathological conditions are in no wise characteristic. The diagnosis cannot be made on them alone. Ever so often, the clinical picture is complicated (XXXVII), even bizarre.

In the endarteritic form, one must consider the possibility of the sudden breaking of a vessel (apoplexy), which, strange to say, remembering the fragility of luetic vessels, is a very unusual occurrence, especially in children, but also in adults (cf. Nonne, No. 15, p. 553). Still, it does happen. Or, one may get a thrombosis, with softening. Again, vessels collapsing (secondarily) in the softened area may lead to hemorrhage. The general symptoms may here be mild. But a hemiplegia results—which either again clears up or persists. In König's statistics seven per cent. of the cases of cerebral paralysis in children belong to this group.

An acute diffuse pontine and bulbar syphilitic affection likewise occurs. In these cases, there may be a rise in temperature, just as this may be lacking in encephalitis and bulbar myelitis. In a majority of the reported cases, the patients were children or young individuals. It should be remembered that syphilitic pontine disease is frequently associated with basal meningitis—or other cranial or cerebrospinal manifestations, which will aid in the diagnosis.

Nor must we forget that a person who once had syphilis—and still has it, or has been cured—may acquire any of the forms of nonsyphilitic encephalitis or meningitis. Should such a patient give a positive Wassermann, it need not mean that the presenting disease is syphilitic.

Keeping these general facts in mind, how make our diagnosis? It is a safe plan to believe everyone syphilitic until the contrary is proven. This admonition should be taken to heart—a lesson one may be taught too late by the blunder of deeming certain persons exempt or inviolate, "who could not by any chance have been exposed" or "where this can scarcely come into question—no outspoken symptoms, big family, with many children and grandchildren, etc., etc." Take nothing for granted—first rule out syphilis in every case.

In taking the history (XXXVIII), inquire as to possible exposure, appearance of primary, secondaries, later symptoms (alopecia, leucoderma, pareses or paralyses, defective hearing, irreactive pupils, corneal opacities, pigmented retinæ, arterial disease, mental changes, etc.) as to pregnancies and offspring: sterility, miscarriages, stillbirths or deaths in early infancy, especially deaths in convulsions, difficult labor, deformities of offspring or snuffles, pemphigus, tuberculosis or marasmus in same. Where congenital lues is suspected, or in sifting data to this end, we make the above inquiries as to the parents (or grandparents) and look the patient over for retarded growth (height), infantilism, retarded or deficient mentality, character abnormalities (behavior) hydrocephalus, rhagades, excoriations, etc., tears and abnormalities of soles and palms, saddle nose, cubital glands, opacities of cornea (earlier corneal ulcer) notched teeth, defective hearing, irreactive pupils, enlarged liver and spleen, osteochondritis, saber legs, joint trouble (especially the knees—hydrops), Olymphus forehead, abnormal genitals, abnormal nails, possibly scaphoid scapula, spastic paralyses (XXXIX). Hysteria, migraine, chorea, epilepsy may also indirectly point to the disease. Especially important is it to inquire whether any of the patient's fraternity has, or has had, any of these symptoms, or whether any died early in convulsions, or of meningitis or tuberculosis. The parents should also be examined and the blood Wassermann taken.

LABORATORY TESTS

Finally, we come to the laboratory tests proper (XL). The socalled four reactions of Nonne, the Wassermann of the blood, the Wassermann of the spinal fluid, the cell content of the spinal fluid and Nonne's Phase I, have become classical, as it were, and merit the first attention; but other tests, some of recent report, may prove of additional, or even decided, importance, i. e., Pandy, Mastix (XLI), colloidal gold, Sachs-Georgi-Meinicke-3, Dold, etc.

The following clinical classification may help us in arranging our data, though often enough it is first through aid of the laboratory findings that we can properly rubric our case: I, Latent leutic, meningeal, processes; II, cerebral or cerebrospinal (or neurological) syphilis; III, syphilitic endarteritis obliterans of Huebner; IV, paresis or taboparesis; V, tabes; VI, hereditary syphilis (XLII).

By latent lues several things may be meant. Usually two or three weeks after infection, the initial lesion appears. There is a focal accumulation of spirochetes at this lesion point—but some have also got into the circulation, and have been scattered here and there in the body—while the body also by this time may have begun to react (XLIII) (biologically) to irritation of invader and his endotoxin products. The evidence of this reaction is seen in the presence of reagins determined by the Wassermann reaction. In many cases the blood Wassermann is already positive at the time the primary appears—in others, it is not yet positive. In these latter cases, we speak of the seronegative stage. As yet, there are no outspoken symptoms; as yet, the disease is latent. But other organs may at this time, or soon after, show reaction to the invading spirochete: the ear does—it may show reaction, even in the as yet seronegative stage—and also the meninges. The spirochete in the meninges starts a chronic process which has a mild acute flareup in the beginning, noticeable or not noticeable, this then usually simmering down to a symptomless state, or there may merely be headaches, first at some later time becoming manifest. We say the disease is latent during this antesymptomatic period—though we know, through our laboratory tests, through our provocative tests, through autopsy findings, that during this stage something is, nevertheless, going on. This latent period may continue for years—many years, in fact—without signs or symptoms referable to any organ. Here the blood Wassermann may, nevertheless, be positive. Some such patients have even never been treated. There are cases of late latency, with no symptoms save the positive blood Wassermann. But there are cases of latency with negative Wassermann.

Schematically, we may arrange our findings in this *latent stage* as follows:

I.

Blood Wassermann:
with 0.2 cm. (in fresh meningitis forms and meningorecidives), positive.
Spinal Wassermann:
in most cases, negative in fresh infections.
in most cases, positive (more or less) (up to 0.2 cm.) in older stages.
Cell count: between borderline and 1000.
Phase one: may or may not be positive—depending on duration and extent of meningeal process.
The colloidal gold test gives a characteristic lues curve.

Should treatment be instituted with mercury or, especially, salvarsan, one frequently gets a Herxheimer reaction, i. e., a passing hyperemic edematous flareup in the syphilis infected meninges, just as such reaction occurs in the skin and other organs harboring luetic processes, causing increase of cells, albumin and liquor Wassermann values, which not only applies to the latent, but also to the patent period. In skin lesions this often shows up several hours after the treatment; in the meninges, it may reach its intensest stage with the third to the seventh, or even eighth, salvarsan injection. According to Gennerich, such reaction is met with in all cases of primary and fresh secondary type. But in secondary cases which have had much treatment, it may be missed. In tertiary lues the reaction appears still less, or not at all.

In cerebrospinal lues our data may be tabulated thus:

II.

Pressure has little diagnostic value (Nonne).
Blood Wassermann positive in seventy to eighty per cent. of cases (xliv).
Spinal Wassermann with 0.2 cm., positive in twenty per cent. of cases. With 0.3 to 1.0, nearly always positive (xlv) (Nonne).
Cell count pleocytosis plus. This is especially strong in meningitis cases (xlvi).
Phase one plus—but not as strong as in IV and V. Only exceptionally negative (xlvii).
Mastix and colloidal reactions are characteristic of lues cerebri or meningitis curve (or combination).

With sufficient treatment these values recede—or, if cure is obtained, turn negative. Or, again, the process may now become chronic. The blood and spinal Wassermann and Phase I remain the same, the cell count about ten to fifteen.

In syphilitic neurasthenia the blood Wassermann is ninety to one hundred per cent. positive (Citron), Phase I, negative, the spinal Wassermann, in seventy per cent., positive.

Syphilitic endarteritis obliterans may come on even as early as several months after the infection. Prodromata of headache, vertigo, insomnia, loss of memory and irritability may be noticed. Gradually one may observe ethical and character changes come on—occasionally a twilightlike state. Pareses or paralyses, due to narrowing or closing or breaking of capillaries or small vessels, occur. Aphasia, epilepsy, mental defect, may set in. On tearing of the pia, a meningitis serosa, with infiltration into the brain substance, can occur, and give psychic changes. (cf. furthermore the syndrome of occlusion of the inferior posterior cerebellar artery.)

The spinal fluid findings are as follows:

III.

One may or may not find a positive Wassermann.
The cell count may be negative, though a slight pleocytosis is rarely absent (Gennerich).
Phase one may be slightly positive or absent.
Pandy is weak plus, opalescent or negative.
All reactions, however, may be absent. According to Kafka, the blood Wassermann is often positive with only 0.5 cm. The liquor Wassermann is negative with 0.5, but with 1.0 is negative or positive.

In paresis or taboparesis our data read:

IV.

Blood Wassermann positive, almost one hundred per cent. A few cases negative (xlviii).

Spinal Wassermann positive and strong in about ninety per cent., if 0.2 c. c. used. Positive and strong in about one hundred per cent. if larger quantity used.
Cell count marked pleocytosis in about ninety-five per cent. (xlix). In a small percentage it is absent.
Phase one usually positive (usually strong). In a very small percentage it may be absent (l).
Mastix and colloidal gold: paresis curve (K).

In tabes the facts are as follows:

V.

Blood Wassermann positive in about seventy per cent.—may be negative in thirty to forty per cent. (Nonne).
Spinal Wassermann positive in about one hundred per cent. if large quantities of liquor, one c. c., used. Negative in about eighty per cent., positive in twenty per cent., if 0.2 c. c. are used (li).
Cell count positive, usually strong, in ninety to ninety-five per cent. of cases (lii).
Phase one positive, usually strong, in ninety-five per cent. (liii).
Mastix and colloidal gold not always characteristic, often of lues cerebri (Kafka).

In cases of epilepsy, neurasthenia, alcoholic pseudotabes, in which syphilis is absent, lymphocytosis and Phase I are negative (99).

The laboratory tests in hereditary syphilis are not as helpful as one might expect—nor are the reports as uniform.

Nonne notes the following:

VI.

Eight cases of juvenile paresis:
Blood Wassermann, strong plus.
Liquor Wassermann, strong plus; globulin plus.
In one case, negative globulin, in spite of strong lymphocytosis.
Six cases of lues cerebrospinalis:
Blood Wassermann strong plus.
Four cases liquor Wassermann, positive.
Three cases globulin plus.
One case globulin minus.
Three cases of epilepsy on basis of congenital lues:
Blood Wassermann, plus; liquor Wassermann, minus; globulin minus.
Three cases of isolated cranial nerve paralysis:
1. Optic atrophy: Blood Wassermann minus and liquor minus.
1. Central deafness: liquor, minus.

Thus Nonne says the liquor may be free (show a negative Wassermann and globulin test) in many cases of congenital lues

Kafka found that the liquor Wassermann in hereditary lues is almost always negative, save in outspoken hereditary luetic diseases like juvenile paresis and lues cerebri, while the blood Wassermann only in the younger years was positive with 0.2 c. c., somewhat longer with 0.5.

J. Breuer's study (100) of the congenitally luetic children of the Berlin Orphan Asylum, forty-two in number, is extremely interesting. Of the infants examined, the following was found: no increased pressure, no albumin, no increase in cells, negative mastix, no liquor Wassermann.

In older children who had been treated, and in whom the blood Wassermann was negative (several tests), and no symptoms obtained, and nerve lues was present (disturbance of pupillary reflex) in but 9.5 per cent. the liquor showed the following: Increased pressure in 68.3 per cent., spinal Wassermann always negative, pleocytosis positive in 42.8 per cent., Phase one positive in seventeen per cent., Pandy positive in thirty per cent., mastix positive in 68.3 per cent.

Thus, in cases in which both blood and liquor give a negative Wassermann, the liquor, nevertheless, evidences pathological findings, especially heightened pressure, pleocytosis and positive Mastix—and this in children having had the best and most thorough treatment. Finally, it may also be remembered that there are cases of congenital lues in which the individual may show neither signs nor symptoms, need not as yet ever to have been ill, yet whose spinal fluid gives evidence of the disease. Thus, Assmann (101) cites a case of a boy of syphilitic mother who was never ill, though of late complained of some headache and showed some inequality of pupils, whose spinal fluid gave a negative Wassermann, was turbid, contained 700 cells, Phase one, plus; albumin, 5. His blood was positive.

Simplifications of the complicated Wassermann reaction, or simpler yet reliable substitute tests, have been brought out in recent years. Of these, the Sachs-Georgi (cf. No. 42, p. 786), Meinicke (102) and Dold modifications have proved very valuable, and not only as tests for syphilis, but tests to be used in gauging the Wassermann reaction when this proved doubtful, or, again, as corroboration of the test, whether plus or minus. Zieler (103) found the Meinicke precipitation test even sharper than the Wassermann reaction. Jänecke (104) also comes to this conclusion after examining a thousand sera with both Wassermann and Meinicke. In 961, the results were similar. In thirty-nine, or four per cent., differences occurred. Of these thirty-nine, twenty-seven were positive with Meinicke, twelve negative. Thus, here, too, the Meinicke proved the sharper test. In these latter cases the histories gave a syphilitic infection, or the primary affect was present, the Wassermann being as yet negative. Some twenty cases of other diseases, in which syphilis was fairly positively ruled out, were also tested with the Meinicke, and proved negative. Richter (105) examined as many as 2,500 cases with both Wassermann and Meinicke, and concluded the latter was as reliable as the former. Here and there cases were seen which would give only the one test or the other.

As the spinal fluid is frequently negative to the Wassermann reaction in early syphilis, the cell count and Phase one, and especially the colloidal gold and normomastix reactions may prove of considerable diagnostic aid. But there are instances in which no laboratory evidence whatsoever is obtainable, and yet the possibility of a sleeping or dormant syphilis comes up. Here, if syphilis is really present, a provocative salvarsan injection often serves the purpose of bringing out a passing positive Wassermann in the blood, mostly twenty-four hours after the injection, also in the fifth, tenth and fifteenth day after. The positive Wassermann in the liquor is first noted some two to six weeks after the provocative injection. If the results prove negative, it is wise to repeat the provocative test about one to one and a half years later, and again examine both blood and liquor. If it is still negative, and there are no symptoms or signs of the disease present, one may with great probability say the syphilis is at an end.

The differential diagnosis of acute brain conditions following trauma and hemorrhage, and the later sequellæ, are taken up in a separate study (l.c.). The acute conditions in connection with the ear are also taken up in a separate study on the eighth nerve

Metastatic Carcinoma of the Pleura

*Report of a Case in Which Tumor Fragments Were Found in the Pleural Fluid**

HENRY M. FEINBLATT, M.D.
Brooklyn

This case is of interest because, in the light of a history of carcinoma of the breast, the discovery of clusters of cells of malignant type in the sediment of a centrifuged specimen of pleural fluid, facilitated the diagnosis of metastatic carcinoma of the pleura.

CASE.—The patient, a married woman, forty-three years old, Hebrew, childless, was under the care of Dr. Joseph Blinder. In 1920 she had a tumor of the left breast, which was accompanied by paresis of the left hand without sensory disturbances. The blood Wassermann reaction was negative. In August of that year complete resection of the breast and axillary glands was performed. Thereafter the patient received x ray treatment over the left lung for a period of six months. She gained in weight and enjoyed good health until August, 1923, when she began to suffer from cough and a sensation of pressure in the chest. On examination, she appeared as a fairly well nourished, slightly orthopneic and cyanotic, middleaged woman. Except for the presence of crepitant râles at the right base, examination was essentially negative. There was no rise in temperature.

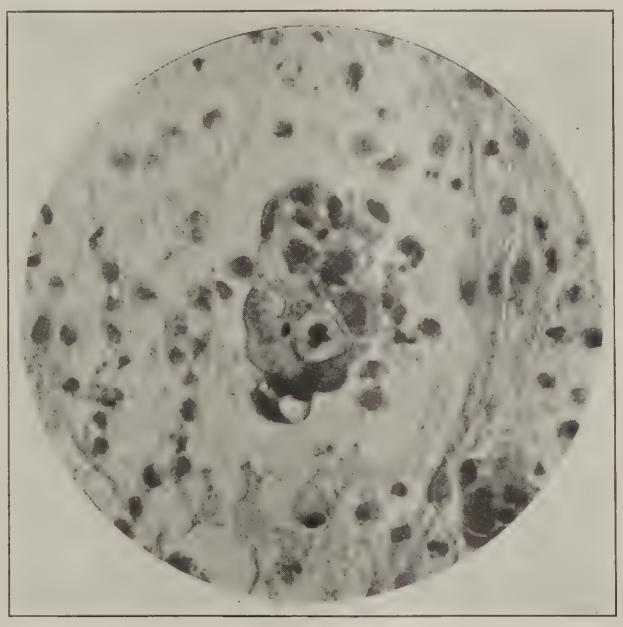

FIG. 1.—Photomicrograph x600 of a paraffin section of a centrifugalized sediment obtained from pleural fluid. This section shows a fibrinous meshwork which incorporates numerous inflammatory cells, among which no single type predominates. Small round, plasma and polynuclear cells are noted as well as numerous large endothelial types. There are occasional compact masses of large cells, the cytoplasm of which, in some instances, shows vacuolization. Amitosis is noted here and there. Occasional signet ring cells are noted. The presence of these various cells other than those of the inflammatory type probably points to a diagnosis of malignancy of the pleural cavity; but the exact classification of the tumor cannot be arrived at for lack of sufficient tumor cell masses. I am indebted to Dr. W. W. Hala for corroboration in the interpretation of this section.

Radiographic examination by Dr. Frederic Elliot on September 9th was reported as follows: With the patient in the horizontal position, the radiographic image showed a complete uniform veiling of the entire right pulmonic field, which, when the patient assumed the upright posture, showed the lower two thirds of the pulmonic field to have a similar uniform veiling bounded above by a crescentic line, convexity outward, with the upper third of the pulmonic field showing normal illumination and structural detail as compared with the opposite side. The left pulmonic field showed no tissue density changes suggestive of a metastatic new growth process. Conclusion: There was a considerable quantity of free fluid in the right pleura.

The chest was aspirated, and clear, amber fluid was withdrawn. A few red cells and many endothelial cells were present in the sediment of a centrifuged specimen. A portion of the sediment was treated with formalin, embedded in paraffin, sectioned, and stained with eosin and hematoxylin. Culture of the fluid was negative. One week later the patient died suddenly of asphyxia while in a sitting posture. Permission for necropsy could not be obtained.

*From the United Israel-Zion Hospital, Brooklyn, N. Y.

DISCUSSION

Attempts to establish a diagnosis of malignant disease from the character of cells found in the pleural exudate date back to Quincke's (1) report in 1882. Warren (2) in 1911, from a comprehensive review of the literature, to which he added three authenticated cases of his own, established the conclusion that very many cells undergoing mitotic division in serous exudates are almost diagnostic of malignant disease, that a small number of such figures is suggestive of malignant disease but is of no certain value in diagnosis, but that in the majority of exudates with malignant disease no division figures are seen. Powell and Hartley (3) state that when the pleura is involved in malignancy, there may be observed cells of large size and irregular shape, often vacuolated in appearance, and with the nucleus pushed to one side, so as to resemble a signet ring. The small number of mitotic figures found in the present specimen would place it in the category of one suggestive of malignancy of the pleura, while the antecedent history is such as to confirm the diagnosis.

It is a fact of considerable interest that, whereas the primary lesion was in the left breast, the right pleura was the one involved, and the left side of the chest was apparently free. It will be recalled that after the breast removal the left chest was intensively treated with x rays for a period of six months. Keeping in mind the experiments of Murphy, Maisin and Sturm (4), it appears possible that the intensive raying of the left side of the chest might have produced a state of local immunity. These authors in 1923 showed that autografts from spontaneous cancers of mice, when replanted into areas previously

exposed to an erythema dose of x rays, failed in the majority of instances (71.4 per cent.), while similar grafts into untreated areas grew in a large proportion of the animals (83.6 per cent.).

SUMMARY

The case report is that of a woman, forty-three years old, with a history of cancer of the left breast and a radical operation three years prior to her immediate illness, who exhibited symptoms, signs and a radiographic picture of pleural effusion on the right side. A paraffin section of the sediment of a centrifuged specimen of the pleural fluid showed large vacuolated cells, some signet ring forms, and a small number of mitotic figures. These findings are in themselves suggestive of malignancy of the pleura, and, in the light of the history, are probably diagnostic of that condition. The left lung was therapeutically x rayed for six months after the operation. This fact offers a possible explanation for the appearance of the metastatic growth on the opposite rather than on the same side.

Mercurial Poisoning by Absorption From Vagina

C. E. RYND, M.D., and M. C. MYERSON, M.D.
Brooklyn, N. Y.

The following case presents clinical features of unusual interest:

Case.—E. H., female, aged twenty-four, white, American, maid, was admitted to the gynecological service of Dr. Rynd at the King's County Hospital, October 5, 1924. She gave the following story: The night before, for the purpose of preventing conception, she had inserted a bichloride of mercury tablet into her vagina. Within an hour she suffered severe burning sensations in the vagina and pain in the pelvic region. She then consulted a physician who advised immediate douching with milk and egg white. This was done. She suffered pain and burning sensations during the night and vomited twice, early in the morning. She then entered the hospital.

Upon admission she complained of burning and excruciating pain in the vagina; moderate pain in the lower abdomen; soreness and sense of pressure in the pelvis, and chills, weakness and drowsiness. She was in severe distress. There was nothing pertinent in her family history or previous personal history.

Physical examination, aside from a slight increase in the number of respirations, was negative except for the vaginal findings. The labia were markedly reddened and swollen, the labia minora being especially reddened and edematous. There was a grayish exudate in the vagina. The urethra was reddened and swollen. There was extreme tenderness on palpation in this region.

There was complete suppression of urine. At the time of admission the palate and pharyngeal structures were free from any pathological process. Until the fourth day the patient showed mild uremic symptoms and her clinical picture presented nothing that other cases of mercurial poisoning do not show.

On October 9th, the fourth day, the pharyngeal structures were swollen and a localized ulcerative area was making its appearance in the region of the left supratonsillar arch. On this day the blood chemistry report was: Urea, 235; creatinin, 6.5; sugar, 73 milligrams to the 100 c. c. of blood. The blood pressure was systolic 104, diastolic 65.

October 10th, the fifth day. An ulcerated area in the throat could be seen to be an area of true necrosis. This was unlike the ulceromembranous lesion of Vincent's angina; no organisms of Vincent-Plaut were found in the smears. There was no similarity to a diphtheritic process, for there was no true membrane, nor was there growth on culture. In fact no organism could be grown from this lesion. It did, however, strongly simulate the necrotic lesion seen in syphilis of the palate or pharynx. The short duration and sudden onset, together with the negative Wassermann reaction, ruled this out of consideration. It was therefore considered to be secondary either to the uremia or to the mercurial poison. The patient had not yet voided. The blood chemistry report was: Urea, 300; creatinin, 8; sugar, 70; Wassermann reaction negative.

October 11th, the sixth day, the area of necrosis above the left tonsil approximated the size of a twenty-five cent piece and extended deeply into the substance of the upper tonsillar pole. The palate and all the pharyngeal structures were swollen, which was not a true inflammatory reaction. The patient's temperature was 99.2° and the pulse 90. The blood chemistry report was: Urea, 330; creatinin, 9.2; sugar, 80. Blood pressure, systolic 94, diastolic 65.

October 12th, the seventh day, the throat showed essentially the same picture. Cultures and smears yielded no bacterial findings. Patient had not voided.

October 13th, the eighth day, a catheterized specimen of urine, less than five c. c., pus cells and renal cells were seen microscopically. The throat picture was essentially the same. Blood chemistry report was: Urea, 411; creatinin, 11; sugar, 76. Blood count, white blood cells, 11,300; polynuclears, 86 per cent.; red blood cells, 2,848,000; hemoglobin, 65 per cent. Patient had not yet voided.

October 14th, ninth day, patient voided for first time, five ounces. Injection and tumefaction of throat structures had disappeared. Area of necrosis was beginning to recede. Until the time that the patient voided her condition appeared desperate.

She was less drowsy but in very weakened condition. Pulse was 110; blood pressure, 75 systolic and 55 diastolic.

October 15th, tenth day, patient voided eighteen ounces of urine. Pharynx was healing. The patient was much brighter. Blood pressure, systolic 114, diastolic 70. Blood chemistry report was: Urea, 414; creatinin, 9; sugar 100. Mercury was isolated in the urine.

October 17th, twelfth day, patient voided urine in large amounts. Pharyngeal structures healing was rapid. Blood chemistry report was: Urea, 417; creatinin, 7.5; sugar, 107. Blood pressure, systolic 100, diastolic 75.

October 19th, fourteenth day, throat entirely healed. There was a sulcus between the upper tonsillar pole and the palate as a result of the destruction of tonsillar and palate tissue. The patient's general condition was markedly improved. She was brighter and sat up in bed a little. Blood chemistry: Urea, 354; creatinin, 5.5; sugar, 123.

October 21st, sixteenth day, the area of involvement in the throat was definitely healed. Blood chemistry report was: Urea, 258; creatinin, 2.5; sugar, 61. Blood pressure, systolic 105, diastolic 75. Patient sat up in bed.

October 22nd, seventeenth day, blood chemistry report was: Urea, 180; creatinin, 1.4; sugar, 80.

October 23rd, eighteenth day, patient allowed up out of bed. Blood chemistry report was: Urea, 162; creatinin, 1.5; sugar, 64.

October 29th, twenty-fourth day, patient discharged as recovered. Blood chemistry report was: Urea, 29; creatinin, 1.1; sugar, 32. The urine was positive for mercury on that day.

TABLE I.—BLOOD CHEMISTRY FINDINGS

Day of illness	Fourth	Fifth	Sixth	Eighth	Tenth	Twelfth	Fourteenth	Sixteenth	Eighteenth	Twenty-fourth
Urea	235	300	330	411	414	417	354	258	162	29
Creatinin	6.5	8	9.2	11	9	7.5	5.5	2.5	1.5	1.1
Sugar	73	70	80	76	100	107	123	61	64	32

The temperature ranged between 98° and 100.2°. The pulse ranged between 80 and 110.

The treatment was as follows: External heat was applied in the form of the electric light bath. Bicarbonate of soda was given intravenously, by rectal clysis, and in colonic irrigations. Caffeine sodium benzoate was used as a stimulant. The vagina was packed with vaselin gauze for its emollient effect.

The experience of our patient does not commend her procedure for purposes of prevention of conception. It is recognized that damage to the kidney function can follow the use of even a moderately strong bichloride douche. The clinical demonstration of this fact has been reported by Bland (1) and Sexton (2) in recent years. In an elaborate study of the question of the absorption of medications from the vagina, Macht (3) not only showed that absorption took place readily, but was so impressed with this phenomenon that he proposed this as a medium for the administration of such medicaments as opium and belladonna when other media were not available. This work was further commented upon editorially in the *Journal of the American Medical Association* (4). It is probable that this type of poisoning occurs more frequently than is believed. We have been able to collect six cases occurring in the past fifteen years in which poisoning was due to the vaginal introduction of bichloride tablets. In each of these cases there was a fatal termination. Schildecker (5) reported three cases with autopsy findings. He concluded that absorption took place through the lymphatics, and was exceedingly rapid. One of his cases terminated within twenty minutes of the introduction of the tablet. It is his opinion that unless the offending tablet is removed within a very few minutes the victim of the accident has little chance of recovery. Millar (6), Conaway (7), and Frederick (8) each report an experience with a fatal case. Recently Weiss (9) covered the subject of mercurial poisoning very thoroughly. He reports upon an accumulated series of one hundred and thirty-five poisonings with only eight deaths. His series does not seem to include poisoning per vaginum however. Nor does he mention having encountered a pharyngeal lesion in his cases. He stresses the presence of an acidemia in these cases and the importance of intravenous alkalinization.

Our patient who had absorbed mercury from her vagina, suffered an anuria for nine days, had an accumulation of creatinin in her blood as high as eleven milligrams to one hundred c. c. an area of localized necrosis developed in her palate and tonsil region which healed simultaneously with the favorable changes in her blood chemistry; and finally she recovered completely from the poisoning.

The palate and tonsillar necrosis which this patient presented, is of unusual interest. One of us is at present engaged in a study of the mucous membranes of the palate, pharynx and larynx in uremia. Barie (10) showed that there was a pultaceous exudate in the tongue and buccal mucous membranes in uremia. Pathologists tell us that uremics show localized areas of necrosis in various portions of the intestinal tract at autopsy. We have felt that the throat lesion which our patient presented was due to the uremia; not so much because of the negative findings for the other possible lesions, but because the throat picture cleared up as the blood content of urea and creatinin returned to normal. Mercury was still present in the urine on the day of discharge; it is hardly likely that this lesion could be accounted for on a basis of local mecurial effect. Barie reported ulceration of the same type in the oral cavity. Ulceration has been found in the esophagus (11) and intestines. The small series of uremias that have been studied would indicate that the severity of the local pharyngeal reaction is dependent upon the suddenness of the kidney insufficiency. In those patients who have a kidney lesion for a long time and uremia develops later there appears to be a mild reaction in the pharynx, palate and larynx; at times none or one that is barely noticeable. The severity of the kidney lesion or the abnormal blood findings in these long standing cases does not seem to affect the intensity of the local reaction of the tissues in the upper air passages.

The authors' references will appear in the reprints.

Practical Therapeutics

TREATMENT OF LOCOMOTOR ATAXIA AND THE PROPER METHOD OF GIVING INTRAVENOUS INJECTIONS OF MERCURY AND ARSENIC

Charles Greene Cumston, M.D.

Geneva, Switzerland

When the physician detects the early signs of a commencing tabes dorsalis, the patient presenting pain of the radicular type, ocular disturbances, paralysis of the external rectus, unequal and irregular pupils, paresis of the pupil reflexes to light, vesical and genital disturbances, absence of the osteotendinous reflexes, anal pruritus, and Romberg's sign, an extremely energetic antisyphilitic treatment should be immediately begun. For a long time it had been supposed that mercurial treatment was without effect on the evolution of locomotor ataxia and some observers even went so far as to pretend that the treatment might aggravate the disease. But in reality, at present, with the newer therapeutic agents at our command, these conceptions are not only erroneous, but are actually dangerous. By taking locomotor ataxia in hand at its onset and attacking the process by energetic treatment, not only can the progress of the disease be controlled, but an amelioration of all the symptoms may be obtained as well, to such an extent in some cases that it is about equal to a cure. It must be remembered, however, that the ingestion treatment is absolutely without effect, that intramuscular injections can only be a complementary treatment destined to continue the good effects resulting from intravenous injections, and that the only treatment that gives favorable results in the process under consideration is the endovenous one. Unquestionably, this procedure offers some disadvantages, the first of which is that it requires considerable skill on the physician's part, otherwise local accidents arise that are not devoid of danger. On the other hand, this procedure obliges the patient to make frequent visits to the physician, which is time consuming and expensive, since the treatment must be prolonged. Consequently it is the duty of the practitioner to make this clear to the patient in the latter's interest.

As has been said, intramuscular injections are absolutely insufficient. Injections of gray oil are useless; those of calomel in oil, recommended by Babinski, are very potent, but unfortunately, regardless of the various improvements made in the preparation of this oil, many patients are unable to tolerate it on account of the excruciating pain which it causes, so that its use should be restricted to tabes with muscular anesthesia, where it works wonderfully. Finally, injections of biniodide or benzoate of mercury are useless therapeutically. Therefore the treatment consists of injections of cyanide of mercury and novarsenobenzol.

The injections of cyanide of mercury should be given in a series of fifteen, at the rate of one every second day; the dose should be one cubic centimetre of the solution which contains one centigram of the drug. The treatment is generally well tolerated. If it produces intestinal disturbances, such as pain in the transverse colon or diarrhea, paregoric or tincture of opium will usually suffice to control these effects. If they persist, however, the treatment should be given up and resumed a few days later.

A series of fifteen injections should be given four times a year and twice yearly should be reinforced by a series of arsenical injections to which reference will be made. The cyanide injections are unquestionably potent and the reason why this treatment is not more general is because it offers certain technical dangers when the procedure is not carried out with exactitude. When from unskillfulness the mercurial salt is injected outside the vein, fearful pain ensues with inflammatory swelling, which soon becomes hard and extends over a considerable area. The patient's general health is affected, even with some elevation of temperature. In most cases sloughing occurs which takes considerable time to cure, and when recovery has taken place, a more or less considerable induration *en masse* results with occlusion of the veins whose permeability represents the patient's salvation. Other accidents may also occur which are equally dangerous. If the solution is simply injected alongside of the vein in a minute quantity, pain ensues with inflammatory swelling and a nodule forms which will occlude the vessel. On the other hand, if the injection is pushed into the centre of the walls of the vein, a nodosity will occur which obliterates the lumen. If the intravenous injection is not given adroitly, if the needle is thrust several times into the vein, the pain caused will discourage the patient and the changes arising in the walls of the vessel from the numerous punctures will result in small cicatrices so that after a time the vein becomes occluded to such an extent that it becomes useless for the procedure. Therefore, the technic must be acquired under the direction of men versed in it, and as this means practical work in a clinic, no mention need be made of it here.

But I would say a word as to the treatment of the accidents referred to above should they arise, and first be it said that the injection should be given slowly, because some few patients will be distressed if the injection is introduced suddenly. A kind of dyspnea results with paleness, due to the arrival *en masse* of mercuric cyanide in the bulbar region. When all the solution has been injected, it is well to aspirate a little blood into the syringe and reinject it. This little maneuvre rinses the needle of all trace of the mercury so that none is left to escape into the tissues when the needle is withdrawn, which otherwise might give rise to mild accidents.

If a little of the solution should be injected along the outside of the vein, the following measures must be resorted to without any delay: Fifty cubic centimetres of sterile water should invariably be ready at hand, to which one centigram of cocaine hydrochlorate is added. A needle is then pushed in *under* the point at which the mercury solution has entered the tissues and twenty c. c. of the cocaine solution injected. The needle is then withdrawn a little and ten c. c. of the solution injected.

TRYPARSAMIDE IN NEUROSYPHILIS*

HERMAN P. HYDER, M.D.

Washington, D. C.

(*Concluded from page* 568)

Nine treatments of tryparsamide and eight treatments of mercury were given and his serology on October 18, 1924, was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid	2 plus
Globulin	2 plus
Cells per c.mm.	6
Gold sol.	5555321000

This patient has improved materially from a clinical standpoint. When placed on treatment it was necessary for him to have assistance when walking; now his locomotion is fairly good, though he still has some loss of control of his legs.

CASE XIX.—Diagnosis, general paresis. This patient gave his age as forty-seven when admitted. He was confused, showed gross memory impairment and speech defect. He seemed to be much deteriorated. On November 5, 1923, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	39
Gold sol.	5555430000.

He received eight treatments of tryparsamide and nine injections of mercury. On April 4, 1924, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	plus
Cells per c.mm.	6
Gold sol.	5544321000.

He was again treated, receiving nine injections of tryparsamide with ten of mercury. On December 4, 1924, his serology showed:

Wassermann, blood	Neg.
Wassermann, spinal fluid, Neg. singles and doubles, 4 plus in quadruples	
Globulin	2 plus
Cells per c.mm.	14
Gold sol.	5554321000.

This patient has responded much to treatment from a clinical standpoint.

CASE XX.—Diagnosis, general paresis. This patient came under our observation on March 9, 1924. Aged thirty-two years. He contracted syphilis in 1917. He was described as showing emotional deterioration and impairment of memory. He was euphoric and indifferent. His pupils were unequal and sluggish in reacting. He was rather poorly nourished. On March 12, 1924, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	34
Gold sol.	5543210000.

He had eight treatments of tryparsamide and nine treatments of mercury. On July 2, 1924, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	2 plus
Cells per c.mm.	8
Gold sol.	5554432100.

He was now given nine treatments of tryparsamide and took mercury by inunction. On November 13, 1924, his serology showed:

Wassermann, blood	2 plus
Wassermann, spinal fluid, Neg. in singles; 3 plus in doubles; 4 plus in quadruples	
Globulin	plus
Cells per c.mm.	6
Gold sol.	2222430000.

This patient is now in good condition mentally and physically, is living away from the hospital and is getting along well.

CASE XXI.—Diagnosis, general paresis. This patient was forty-seven years old when admitted May 16, 1924. He entertained delusions of grandeur with the other symptoms of the expansive type of paresis. He gave a history of chancre, 1911. On May 21, 1924, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	18
Gold sol.	5554421000.

He had ten treatments of tryparsamide and his serology on September 4, 1924, was as follows:

Wassermann, blood	1 plus
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	8
Gold sol.	4555432000.

He was given an additional ten treatments of tryparsamide, four injections of mercury and some mercury by inunction. On February 3, 1925, his serology was as follows:

Wassermann, blood	1 plus
Wassermann, spinal fluid	2 plus
Globulin	Neg.
Cells per c.mm.	2
Gold sol.	5544320000.

This patient has made a complete change mentally. He is quiet and orderly; all delusions have disappeared and he is in excellent condition physically.

CASE XXII.—Diagnosis, general paresis. This patient is thirty years old and gives a history of chancre twelve years ago. When admitted he was in only fair condition physically, while mentally he was somewhat deteriorated, showing the clinical picture of paresis. On May 9, 1923, his serology was as follows:

Wassermann, blood	4 plus
Wassermann, spinal fluid	4 plus
Globulin	2 plus
Cells per c.mm.	22
Gold sol.	5554321000.

He was given ten treatments of tryparsamide when his serology showed:

Wassermann, blood	Neg.
Wassermann, spinal fluid	4 plus
Globulin	3 plus
Cells c.mm.	9
Gold sol.	5554320000.

With no additional treatment his serology was as follows, January 16, 1924:

Wassermann, blood	Neg.
Wassermann, spinal fluid	4 plus
Globulin	4 plus
Cells per c.mm.	53
Gold sol.	5544432000.

When about six months had elapsed since his treatments were discontinued, he was given another ten intravenous injections of tryparsamide and on November 13, 1924, his serology was as follows:

Wassermann, blood	2 plus
Wassermann, spinal fluid, Neg. in singles, 4 plus in doubles and quadruples.	
Globulin	4 plus
Cells per c.mm.	4
Gold sol.	4555532000.

While this patient's serology has changed slowly,

*This paper was read before the American Congress on Internal Medicine, March 9 to 14, 1925, at Washington, D. C.

he has improved markedly from a clinical angle. He is quite a contrast to what he was when first seen.

Tryparsamide was given in three gram doses at weekly intervals to these patients. Salicylate of mercury was given in one grain doses and blue ointment was given by inunction. Each patient's eyes were examined during the period treatments were in progress, but no acute eye symptoms were discovered.

Of the twenty-two cases reported, sixteen were general paresis, two were taboparesis and four were cerebral syphilis. Of the twenty-two cases, fifteen, or sixty-eight per cent. of the whole number treated, showed improvement. Two of the paretics were very unfavorable cases for any kind of treatment and they were put on this treatment for reasons other than the expectation that any great benefit might result. Two others were poor risks. Sixteen paretics were treated; eleven had tryparsamide with some form of mercury; five had tryparsamide alone. Seven were unimproved; two of this number died. Nine paretics out of the sixteen showed improvement. Both cases of taboparesis improved. Each of the four patients having cerebral lues who were treated with tryparsamide, showed much improvement.

An effort has been made, in noting the condition of the patients, to consider them from a clinical viewpoint as well as from a laboratory level; but, as stated before, it seems to me that the clinical angle is the more important, for little is accomplished when a patient's serology becomes less strongly positive while his mental and physical condition does not show corresponding improvement.

Those who have made a thorough study of neurosyphilis and understand the makeup of the tissues involved, and the nature of the existing pathology, are hesitant when any new drugs or new methods of treatment are heralded as a panacea for this condition. Among the results thus far reported, probably those given by Lorenz and his coworkers are most impressive because the period intervening, since treatments were instituted, was quite long. The comparison given by Solomon and Veits between tryparsamide and the other arsenicals is also quite interesting and instructive.

Because of the small number of cases under consideration the writer will not attempt at this time to discuss the relative value of this and other methods of treatment, aside from merely pointing out that the final results obtained with tryparsamide as with other modes of therapy, depends largely upon the stage to which the disease has progressed when treatment is instituted. The sooner the case is diagnosed and put on treatment, the more favorable the results to be expected.

Treatment of Rheumatic Fever with the Ethyl Ester of Phenylcinchoninic Acid.—C. Philip Miller and Ralph H. Boots (*Journal of Laboratory and Clinical Medicine,* October, 1924) treated eight patients ill with rheumatic fever with the ethyl ester of phenylcinchoninic acid, the method of administration being the same as that described for neocinchophen, i. e., one gram of the drug each hour until the appearance of some evidence of therapeutic effect or of drug intoxication, at which time the drug was discontinued for that day. On succeeding days the patient was kept well under the influence of the drug and as free as possible from toxic symptoms, or in other words, an effort was made to maintain the maximum subtoxic dose. The amount varied considerably and had to be determined for each patient, but in general corresponded to the dose which was necessary for neocinchophen. The period of administration varied from four to forty-one days. Coincident with the relief of the arthritis there occurred a disappearance of fever and rapid heart rate. As with neocinchophen, a bradycardia was frequently noted during the first week of administration. This drug also gave rise to toxic symptoms, similar in character to those of salicylism, but milder in degree. While no definite general conclusions can be drawn from this small series, the possibility is suggested that the ethyl ester of phenolcinchoninic acid is less toxic than neocinchophen.

Intravenous Use of Mercurochrome.—F. S. Hopkins (*Boston Medical and Surgical Journal,* October 16, 1924) says that his experience with the intravenous use of mercurochrome has not equalled his expectations. Of twelve cases there were five in which it was of no benefit, five of temporary or doubtful benefit, and two in which it seemed to be of definite value. But even in these two cases it is impossible to prove that the results obtained were due to the use of mercurochrome. The reactions following its use were not alarming, except in one case, in which a rapid and irregular pulse followed; this responded promptly to digitalis. He does not believe that the intravenous use of mercurochrome should replace any generally recognized indication for surgical treatment. Still he feels that in cases of infection that are not readily controlled by simple surgical procedures it is of sufficient value to warrant continued trial. In cases of septicemia he thinks it should always be used, for it offers a hope of cure in an otherwise usually fatal condition.

Complications Following the Use of Mercurochrome—220 Solutions.—Ben N. Wade (*Northwest Medicine,* November, 1924) says that while mercurochrome-220 is a valuable germicide, and can ordinarily be safely used, the following precautions should be borne in mind:

1. It should not be used in deep and poorly drained cavities or sinuses continuously over a long period of time. When indicated in such cases, it should be used at intervals.

2. When used intravenously, it should be given only in urgent cases and then with caution.

3. Strong solutions should not be used until after weaker strengths have first been tried out.

4. Stomatitis may result from the use of weak solutions, one per cent solutions having produced it

The Morphological Factor in Respect of Rheumatism and Other Affections of Joints

F. G. CROOKSHANK, M.D., F.R.C.P.
London

Whenever we seek to enumerate and appraise the many and various factors that may and do determine the incidence of rheumatism and other affections of joints—whether in respect of persons, or of special parts and structures in particular persons—there is one which, in the country of Oliver Wendell Holmes at least, should be ever present to our minds. I refer to that etiological component classically indicated by the theory of the *locus resistentiæ minoris,* but better understood when we declare, in the words of the immortal and philosophical Deacon, that "the weakest part must stand the strain." It is sometimes said, and not without some measure of truth, that this proposition, like most, if not all scientific theories, depends for its proof upon use of the artificial fallacy known as the *petitio principii,* or, "begging the question." That is to say, we, too commonly, find proof that the part affected is really the weakest, in the fact that it is indeed the part affected; and we seek to demonstrate that the weakest part will break down the first, by showing that it is certainly the weakest. Now, although this sort of circular reasoning is immensely popular in medical circles since the abandonment of the study of logic, and although we have come to believe that nothing is necessary for the discovery of truth save observation of what we call facts, there is something that can properly be said, in support of the Deacon's thesis, that does not involve the adoption of any fallacious reasoning. We can show, for example, that the structures and organs which are most often affected are those found to be inferior when some standard other than the medical is adopted; and we can also show that, in many cases, affected parts are those which must be judged inferior by the anthropologists or comparative morphologists. If we do this we achieve a scientific demonstration. For the difference between a truly scientific demonstration, and one that is unscientific, is this: scientific proof depends upon and brings to our minds considerations outside the sphere of the original problem, while unscientific proof teaches us nothing new, opens up no new horizon, and brings us back in our own tracks to the point from which we started.

My first proposition then is that the parts and tissues most easily and most often affected by environmental and accidental stresses are those which, judged by the standards of comparative morphology, are distinctly inferior: that is to say, are those which are the less evolved, when compared with their like, and which exhibit reversionary characters in one or other respect, or at any rate preserve embryonic or infantile features.

Indeed, it is by the morphological characters of any part that the functional organization thereof can best be judged.

Sometimes we can obtain no direct evidence as to the morphological characters of the parts chiefly affected, as we say, by certain diseases; but we can generally obtain such evidence in respect of correlated structures, and so judge of what is hidden.

For example: most asthmatic and croupy infants possess only two lobes to the right lung, and an epiglottis that is defective in form. We can infer as much when we see the snubby nose and the tiny nasal orifices. Most children who come before us with acute mastoiditis have aircells which are badly developed. We should guess that when we observe how defective are their auricles and lobes. Many cases of socalled neurotic abdomen have loose mobile cecums and kidneys: sometimes persistent Meckel's diverticula. I have diagnosed the latter abnormality when I have noted the patient's fissured tongue. Children who wet the bed when young, and in later life are sexually ineffectual or perverted, display as infants, if male, an undifferentiated scrotum; if female, labia defective in an artistic sense.

Indeed, the less any external part or member conforms to the Greek standard, the more does it approach the standards of primitive races and the anthropoid apes; and the more likely is it, and the organs correlated with it in function, to break down under strain.

The liability is even greater if, not so much is any one primitive type conformed to as is the part or organ dysharmonic, and a complex of several primitive or recessive types.

After all, this is only to say what every artisan

knows; that, when certain parts of a complicated structure are below the best standards in respect of form and finish, they will certainly break down under stress sooner than should be the case, and are probably made of inferior material. Moreover, a simple or harmonic design is an excellent gauge of probable efficiency; while a motor car or one hoss shay that is, in respect of its lines, a compromise between two types (each excellent in its way) is pretty sure to be a practical failure.

How can we apply these general principles to the case in hand: the liability to rheumatism and other arthritic affections? Clearly, we have to deal with at least two categories, or classes, of inferiority. There is the general liability to infection, or to metabolic error; and the particular liability of particular structures to be affected, in presence of infection, metabolic error, mechanical strain, and so forth. It has long been recognized that persons liable to acute rheumatism tend to conform to a certain anthropological type: there are likenesses in respect of complexion and skin, hair and eye coloring. Again, the French believe firmly that chronic arthritics possess what is called the arthritic diathesis: that such persons are liable to certain nonarthritic maladies, notably psoriasis and other affections of the skin. All this is true enough, in the sense that it is a generalization from experience. And I have the impression that those who suffer from acute rheumatism are persons in whom the lacunar system—the lymphatic and serous complex—offers less resistance than is normal to certain infections. On the other hand, chronic arthritics perhaps share in common some inferiority of certain tissues. At any rate, it is not strange that children in hospital with rheumatic fever, and chronic arthritics at spas and watering places, should display the kind of likeness to each other that Dr. Draper has demonstrated as observable, in terms of precise measurement, between persons suffering from certain other diseases. (See *Human Constitution*, 1924.)

It is not, however, with this category of inferiorities and liabilities that I am anxious now to deal, and I would say definitely, both as a challenge and as a statement of experience, that the affected joints and correlated structures of persons who are the subjects of rheumatism and the rheumatoid affections are so often markedly inferior, from the point of view of the morphologist, that we are justified in asserting a correlation between morphological inferiority and liability to certain joint affections. That is to say, persons who exhibit such inferiorities are more liable (*caeteris paribus*) than are others to break down in respect of the inferior parts, under stress. The importance of this correlation is twofold: it gives us a guide in prognosis, and it is of educative value. Our prognosis and our treatment, of one order when etiological responsibility attaches chiefly to occasional or accidental stresses or strains, must be quite otherwise when such responsibility is to be chiefly allotted to "original sin" in respect of functional inadequacy or structural defect. We should never say of any human being, as we may say of a motor car, that it is "not worth repair." But we can at least avoid "repairs" that impose a greater strain than can well be borne, and we can refrain from promises that are as delusive as the means employed are costly.

Before referring in general terms to the kind of characters met with in the hands, the hips, and the lumbosacral spines of certain arthritic patients, there are one or two points of some interest that may be noted. The kind of defect met with, in respect of configuration, or morphological inferiority, is usually one already indicated when the cartilage is laid down. It is existent, as a rule, before osseous outlines are defined. The cartilaginous and fibrous tissues are themselves inferior as materials (or hypoplastic) as well as in modelling. Sometimes there is osseous hypoplasia as well, as in many rheumatoid young women. But the osseous hyperplasia that is so common in adults and seniles, and sometimes occurs in the young, appears to me almost always best considered as a well intentioned but ineffective compensation: a compensation that, like many others, goes sometimes to excess. Another point is that, in some cases, as in tabetic arthropathy, there is what an Irishman may call regressive tissue hypoplasia, under trophic influences. Trophic influences, so largely ignored by the physician and physiologist (because not normally obvious in the decentralized, fully organized and specialized community of cells and organs that we call an adult) are more obvious, and more active, in the centralized, unspecialized and undeveloped or regressive communities that we call the child and the senile respectively.

But differently; in the normal adult there is greater local autonomy. A normal adult, if rheumatoid, is usually monoarticular, from the clinician's point of view, because of local defect or local strain, and because what with him affects a part does not greatly affect the whole.

But the child, and the senile, if affected locally, suffer *as wholes*. They are affected, not only locally by local stresses, but generally by whatever weakens the whole and lowers central trophic control and stimulation. In fact, the older or the younger the patient, other things being equal, the greater the tendency to generalized affection. The better developed, the more normally adult the patient, the greater the tendency to localization in a joint particularly affected by stress, or specially defective morphologically.

Turning now to some specific points, if we examine the hands of people about us we find that, roughly speaking, two types emerge as differing from the mean, and yet as being congruous, or harmonic. Of these, one is long and osseous; the other, short, plump, and supple. The long and osseous type corresponds, in a racial sense, to that of the non-Mongolian primitive peoples, and, pathologically, to Marie and Cushing's hyperpituitary *main en large*. The other corresponds racially to that of the Mongolian races and, pathologically, to the hypopituitary *main en petit*. But I am only speaking in broad terms. Now, grouped around these two types, and the third "mean" or normal hand of white races, we find others. Some of these are composite, or mixed—dysharmonic. They are often rheumaticky hands. Others, while conforming in a way to the second, hypoplastic, or racially Mongolian type, are yet something more. They remind us of the hands of the Mongolian imbecile, or of the achondroplastic, or of something else! And such hands as these are often seen among those who are subject to rheumatic fever,

or the polyarticular rheumatoid affections. We note, n these cases, amyotonia, short incurved little fingers, small thumbs, an irregular digital formula, short, or llformed last phalanges and irregular metacarpal arrangements. Often enough the patient will say: 'Yes, Doctor. Have I not funny hands. And my feet are just the same!" So, on removing the stocking we may see a chubby foot, with a row of absurd oes all the same length as in some Oriental peoples. And so on.

Many varieties of this kind of morphological inferiority might be mentioned, but I can only here refer to one: that which my friend André Léri has described as *Pléonostéose familiale*. Here, in this familial, almost congenital, condition or disease, we have to do with a malformation and compensatory hyperosteosis that seems, as it were, both pathological and atavistic. For the hands of the patients are, as are the hands of the Lapps, and as are in less degree those of not a few persons who become the subject of true osteoarthritis. In respect of this notable affection, and of many other structural and skeletal conditions—half disease, half deformity—the remarkable articles in Fascicule XXII of the *Nouveau Traité de Médecine* should be consulted.

Now, if we turn from the hands to the hips, we find that Calot, of Berck-sur-Mer, has shown, what some of us had long thought, namely, that in many cases of what have been called special affections of the hip, whether in youth or in age, and in many cases of socalled arthritis deformans of the hip, we have really to do with a hip that is, in principle, a more or less marked instance of a congenitally dislocated hip. Acetabular imperfection is clearly marked. So, once more is the Deacon justified. We have a long series, as it were, of cases with congenital deformity, or grades of deformity, passing from the frank congenital dislocation at one end of the scale to senile arthritis at the other: to osteoarthritis, that is, supervening in respect of a hip which, in early life, did not quite develop, as we say, normally.

We all know how commonly the hip is affected by rheumatism and by rheumatoid disorders. Why should it be that, in such an important structure, there should be, as I for one believe is frequently the case, such a range of developmental variation as Calot's work suggests?

Some hint of a solution is afforded if we pay attention to the work of Klaatsch, and Sera (alluded to in my recent little book *The Mongol in Our Midst*) which seems to have established the existence of at least two types of femur among mankind —fossil and extant—and the great anthropoid apes. Of these, the one is coarse and the other slender: in the one the neck is set to the shaft at a less open angle than in the other; and there are other differences, of torsion and the like, which are important. The two types correspond to, and are correlated with, the two hand types already described. In the second —the Mongol-Orang type—there is a greater tendency to laxity of the hipjoint; for the orang has no ligamentum teres: and the acetabulum is not as in the other. Now, as Sera suggests, the first type is the less, the other the more, adapted to arboreal life; but, as I have shown, the first type is adapted to squatting with the lower limbs in vertical planes; the second, to the Buddha position. And—this is the important point—while both these types are met with among the socalled white races (though less commonly than a middle, or normal type) yet, very frequently, not only is congenital dislocation of the hip of the typical kind, but the minor degrees of that condition (described by Calot as associated with forms of arthritis) very common in hypogenetic persons who exhibit Mongolian or semi-Mongolian characters. My suggestion is that many of these cases of imperfect development in a morphological sense that in later life have rheumatoid changes clearly superimposed, are persons who, when in the embryonic, fetal, or infantile stages of life, hesitated at the crossroads of development by reason, as Samuel Butler would have said, of confused memories. This is not fanciful: it works. The facial characters alone give the hint: the x rays make for assurance. And this is the central fact: the hip joint is a pivotal structure in more senses than one, for human and ape types may be grouped more surely in respect of the morphology of the hip and femur than of any other structure or organ that can be suggested.

Sacralization, as it is called, of the fifth lumbar vertebra is a cognate topic, and for the best of reasons. There is a definite correlation between the second or Mongol-Orang type of femur and pelvis, and a tendency to sacralization of the fifth lumbar vertebra. This is because the Buddha position tends to require a firmer lumbosacral support for the spine than does the ham, or buttock squatting position, with the lower limbs arranged vertically.

Now the subject of sacralization, which has been so ably discussed by Meynadier, in a recent *Thèse de Paris*, is one that is of double interest in connection with the rheumatoid affections. In the first place, abnormalities of the lumbosacral spine are organ inferiorities in the sense of Adler: they are *indicia*, not merely of skeletal inferiority, but of cerebrospinal, and so of psychological imperfection and perhaps of trophic functioning. Secondly, they exemplify once more the Deacon's teaching, for, as any one may satisfy himself, there is a definite correlation between them and the spinal incidence of infective, traumatic, and metabolic stresses. At the same time it should not be forgotten that persons displaying these abnormalities or inferiorities are more prone than are others to complain, after accident or strain, or lumbar puncture, of pains and of rheumatisms that improve greatly after the attention given by osteopaths and denied by the orthodox. However envisaged, the lumbosacral spine and the hipjoint form together a complex that is of enormous anthropological significance and pathological importance.

In drawing the attention to some unconventional lines of thought and observation, I am anxious not to be thought careless of the importance of what may be called "more practical considerations." But it is as least as practical to distinguish between the effects of a strain or infection upon a normal joint, and the marked effects of a slight strain or infection upon a defective joint, as it is to resect the colon, or embark on a course of vaccines against an unknown bacillus, when a congenitally weak hip is yielding under mechanical strain! In any case, truth cannot fail to be useful, while there is no need for it to be

feared, save by the charlatan. And there is a charlatanry of thought within the pale as well as a charlatanry of action, outside it. A disease is no thing with external existence and objective characters. Disease is a function of at least two variables, whether we call them soil and seed, organism and environment, or one hoss shay with Deacon as a load. We must study both variables, and appreciate both variables, never losing sight of the truth that it is the relation between them that constitutes the disease, and that is evidenced by the symptoms. What we call organic disease is the effect of the relation, and not the cause of it.

The broader our conception of the complexity of this relation we call disease, the better our diagnosis. For, after all, diagnosis is appreciation of the patient's present situation, and of how it has been brought about. It is not the summary identification of the obvious symptoms and signs with an account given in a textbook and known by a class name.

Endocrines in Relation to Rheumatic Fever and Rheumatoid Arthritis

LLEWELLYN JONES LLEWELLYN, M.B. (Lond.)
London

To look at timeworn problems from an unwonted angle is always interesting and not seldom illuminating. For that ancient maxim *Audi alteram partem* is but too often forgotten in the sphere of medicine as elsewhere. Especially in the domain of etiology are we likely to overlook the "other side." Thus, we have been affirming so loudly and so long that "rheumatic" fever must be an infection that the obsession has nigh blinded us to all aspects of the disorder that might clash with the preconception.

But assuredly there is another side. One of etiological import, too, and not necessarily antagonistic to the infective hypothesis but complementary thereto. Thus, important as bacteria are, they are still of less importance than the cells and tissues they infest. For if these latter provide not suitable cultural conditions the invading microbe fails of its end —infection. How urgent then the call for more light on what may be termed the intermediary pathology of rheumatic fever! On those important factors or conditions that determine whether an intruding microbe shall achieve infection or suffer mere sterile implantation, and to development of this aspect we now proceed.

Now, the phenomena of "rheumatism" in childhood clearly indicate that it is not primarily a disease of joints—surely an etiological hint of prime significance. Nevertheless, when in older subjects joint swellings dominate the clinical picture we not only forget this point but allow their presence to color all our conceptions of the nature and etiology of the disorder, and straightway for many this widespread constitutional disorder shrinks in its clinical content and becomes in effect merely an arthritis. Moreover, despite the *sui generis* character of the joint swellings their fleeting migratory habit and lack of residual changes—so foreign to other infective or streptococcal arthrites—we nevertheless assume them to be of like origin. Apart from this, does not their specific response to salicylates, comparable only to that of colchicum in gout, of itself suffice to stamp them as *sui generis* seeing that other infective or streptococcal arthrites are rebellious thereto.

But to resume, does not the difference—*qua* joint involvement—between the rheumatism of childhood and the rheumatic fever of older subjects indicate that the joint swellings do not represent a further stage in evolution of the life history of the disorder. For presumably the basic etiological factors of the rheumatism of childhood—in view of their cardiac manifestations—are common also to the rheumatic fever of adolescents or adults.

Whence then the difference in clinical facies prior to and after the passing of puberty? Must not the immature tissues of a child differ profoundly from these same tissues when activated by the genital hormones that flood the circulation at the advent of puberty? Surely it is these tissue contrasts that dictate the disparate nature of the clinical reaction to the rheumatic virus, whatever its nature?

Nowadays we think much, and rightly, of the malign effects of infection on the endocrine glands; but have we not here a clear indication that the process is reversible, viz., that if infections can modify the endocrine glands, so also can the endocrine glands modify the tissues' reaction to infections? Is not this further inference then justified, viz., that hereditary or congenital endocrine disabilities may profoundly modify the reaction of the organism to infection? May it not yet transpire that an infection say falling e. g., on a subthyroidic substrate may evoke a different reaction than if it fall upon one of normal endocrine constitution? It can scarcely but be so since we admit that the thyroid and other endocrines influence profoundly the metabolism of all the body cells.

Now, there is, I think, considerable evidence that the hereditary and familial tendencies to rheumatic fever are transmitted via the endocrine glands—that *ab initio* children of socalled rheumatic stock are handicapped by their heritage of endocrine and notably thyroid instability. That under the influence of infective nutritional and other factors the latent tendency to generalized dysfunction of the endocrine and autonomic systems is unmasked—revealing itself in divers ways. Hence the reason why these rheumatic children are given to idiosyncratic reactions, display a penchant for disorders that are paroxysmal and periodical, and these moreover prone to clinical reaction and alternation.

Does not the very diversity of the elements of what Cheadle termed "the rheumatic series" in chil

ren clearly indicate that infections are but excit-ng factors, evocative rather than causative and uite subordinate in importance to the inherited pre-isposing factors—the tendency to endocrine imbal-nce with its correlated and clinically indissociable utonomic imbalance. Let us now proceed to ascer-ain what evidence there is that the clinical vagaries f the rheumatic child are linked up with endocrine bnormalities.

IORBID PROCLIVITIES OF THE RHEUMATIC CHILD

The essential attribute of the rheumatic child is nstability or hypersensitiveness. He is, par excel-ence, of the hypertonic neuropathic kind, highly maginative, excitable, very susceptible to cold, and eadily fatigued. All, again, have noticed their ten-lency to emotional crises, night terrors, stammering, nuscular tremors, athetotic movements, what Good-art terms subchorea and last but not least, their endency to tetany.

Their inborn instability is further disclosed by ymptoms indicative of vasomotor ataxia—cold ex-remities, dead fingers, chilblains, or true Raynaud's lisease. Also, by their proneness to fleeting urti-arial or erythematous rashes, to cyclical vomiting, outs of epigastric pain with diarrhea, or mucous olitis, not to mention asthma, and migraine, and noreover by the striking manner in which these arious syndromes may alternate with each other.

In reviewing this veritable medley of disorders, he conclusion seems inevitable, viz., that they are he outcome of an inborn predisposition—a diathesis f, I believe, a neuroendocrinopathic kind. Endeav-oring to find some common etiological bond for these livers syndromes, I some time since suggested that the live link in rheumatic as in asthmatic heredity was the transmission of a tendency to protein sensi-ization. For recalling the resemblance obtaining between the phenomena of serum sickness and rheu-matic fever such an hypothesis might explain the otherwise inexplicable interplay of the articular and abarticular manifestations of the latter disorder. But even so, through what medium is the hereditary transference of a tendency to protein sensitization secured? Does it constitute another phase of endo-crine or glandular heredity?

ENDOCRINE INSTABILITY IN RELATION TO THE RHEUMATIC CHILD

The apparently disconnected elements constituting the rheumatism of childhood seem highly suggestive of some inborn state of endocrine and autonomous imbalance. I use the term imbalance advisedly, for, imbalance connotes instability. Now, instability in the endocrine sphere implies neither hyperfunction nor hypofunction, but an alternation or mingling of the two states—with correlated variations in the sympathetic system in the direction of excitation or depression.

Thus, in common with others, I have met with evidences of hypothyroidism, e. g., solid edema, as well as of hyperthyroidism in Graves's syndrome. Indeed, as we know, the cardinal symptoms of Graves's disease may persist despite the development of myxedema through thyroid exhaustion. Recog-nition of this fact, viz., that signs of hypersecretion may coexist with those of hyposecretion, will, I think, help us to unravel the tangled skein presented by the phenomena of rheumatism in childhood.

EVIDENCES OF HYPOTHYROIDISM AND HYPERTHYROID-ISM IN A RHEUMATIC CHILD

Out of the somewhat bewildering congeries of morbid signs and symptoms presented by children of rheumatic stock, their liability to tetany and also to symptoms of vasomotor ataxia stand forth from the endocrine viewpoint as the most arresting features.

Their proneness to tetany has long been known. Remarked by Goodhart it was recently emphasized by McCarrison's observation that "Rheumatism is frequently associated with tetany." Indeed this tendency to tetany seems to run like a thread through the life history of the disorder, as it crops up again in the rheumatic fever of older subjects. It may arise actually during its course, but more often after its close when—as I have observed—it may form an interconnecting syndrome between rheumatic fever and a subsequent rheumatoid arthritis—its origin attributable perhaps to the hypothyroidism that so often follows the former disorder. Moreover, just as at the close of rheumatic fever symptoms of Graves's disease may arise, so also, in the declining stages of tetany have Kahn and Falta seen the thyroid enlarge with marked symptoms of exophthalmic goitre.

Now, tetany is avowedly due to thyroparathyroid defect. Its association not only with Graves's syndrome, but also myxedema, is acknowledged, and more especially with goitre. Its kinship with these disorders is the more significant in that they are all distinctly of hereditary and familial trend—especially goitre. The children of the goitrous tend to be goitrous—but this not necessarily through hereditary transmissions as in regions where goitre is endemic the same causes may be operative in parent and offspring. On the other hand, if the goitre be accompanied by thyroid insufficiency, this subthyroidic taint is hereditarily transmitted to the offspring. Now, women when goitrous and subthyroidic are extremely prone to tetany—a symptom in itself of thyroparathyroid insufficiency, and the subthyroidism thus disclosed is handed on to their offspring with its correlated liability to tetany.

Now, children of rheumatic stock are also liable to tetany, and therefore similarly suspect of thyroparathyroid inadequacy. Moreover, my own experience leads me to suspect that a subthyroidic taint in parents entails on their offspring not only a special liability to tetany, but to rheumatism and rheumatic fever, as also to the rheumatoid or atrophic and osteoarthritic or hypertrophic types of arthritis deformans. For I have noted the following points which appear to be of etiological import:

Firstly.—That in regions where goitre is endemic the incidence of rheumatic affections appears to be abnormally high. So much so, that practitioners migrating from a nongoitrous to a goitrous locality, are immediately struck thereby; not only by the number of cases of rheumatic fever they meet with, but the frequency with which cardiac lesions—not preceded by rheumatic fever—occur. Also, by the frequency with which cases of rheumatoid arthritis are encountered, and incidentally, I may remark, that as

far back as 1902, I pointed out the frequency with which rheumatoid arthritis and Graves's disease coexisted (1). Moreover, having observed in instances of preexisting Graves's syndrome that recession of the thyroid swelling was followed by rheumatoid arthritis, I suggested the administration of thyroid gland (2), the good effects of which in well chosen cases of rheumatoid arthritis are now well established.

Secondly.—That if rheumatic fever develops in the child of a goitrous mother it shows a strong impetus to chronicity, being rebellious to salicylates. Also, if it occurs in a child, not necessarily with a mother actually goitrous, but living in a region where goitre is endemic, it may show the same peculiarities. Now seeing that goitre and subthyroidism are frequently associated, and that subthyroidism is markedly hereditary, it seems to indicate that the hereditary and familial tendencies to rheumatic fever are transmitted through the endocrine glands—notably, but not exclusively the thyroid. Also, that the nonresponse to salicylates is linked up in some obscure way with thyroid or thyroparathyroid defect or instability.

Thirdly.—That this obduracy to salicylates relents if in addition thyroid therapy be invoked—the thyroid appearing to activate the otherwise impotent salicylates. This renders more plausible my suggestion that this rebelliousness to salicylates is bound up in some subtle way with the thyroid deficiency or instability. Now, apart from definitely goitrous regions, the present fashion of exposing the necks clearly shows that goitre is far more common in adolescent girls than was previously suspected. Accordingly, our search for the minor evidences of thyroid insufficiency in such subjects is urgently indicated. The more so if, as I believe, subthyroidism connotes a special liability to rheumatic affections. For if so, it follows that the original predisposing factors that make for the development of rheumatism in childhood, and of rheumatic fever in older subjects, ought to be sought for in those conditions—intrinsic and extrinsic—that determine the production of subthyroidism.

To resume, the subthyroidism of rheumatic children is further tokened in that they are often ill nourished, do not grow or put on weight, like other normal children of their own age, i. e., arrest of development. Again, their temperature is often subnormal, their skin dry and harsh, their hair sparse on scalp and outer side of eyebrows, with deficient appetite and constipation—signs all of them of hypothyroidism.

Additional evidence of their subthyroidism is to be found in their tendency to vasomotor ataxia—symptoms due to correlated lowered excitability of the sympathetic system, viz., slow pulse, cold hands and feet, dead fingers, chilblains and true Raynaud's disease.

Is it not significant, too, that the disorders—urticaria, erythema, migraine, asthma, mucous colitis—to which rheumatic children are prone, occur with notable frequency in subthyroidic subjects? Still more that such often undergo attenuation or cure by thyroid therapy? But—it may be objected—are not these various affections often ascribed to protein sensitization and moreover prone to hereditary transmission? Admittedly so, and the same is perhaps secured by endocrine heredity. For there is some evidence that the protective mechanisms of the thyroid extend to anaphylaxis.

Thus, Mante tells of a woman—sensitized to eggs—who nevertheless could eat them with impunity when pregnant, and then only. Now, thyroid secretion increases during pregnancy, and Mante suggests that her tolerance of eggs during pregnancy, was due to this autothyroid therapy. Again, Levi and Rothschild note that the victims of migraine, urticaria, asthma, and allied affections often—during pregnancy or the menopause—enjoy immunity from these disorders. Moreover, having observed that many of the aforesaid syndromes respond favorably to thyroid, they are inclined—like Mante—to conclude that the freedom enjoyed is due to the enhanced thyroid secretion incidental to these periods. Lastly, Leon Kepinow found that if—after a protein injection—thyroid were given by the mouth a day or two prior to the secondary inoculation, it minimized or prevented anaphylactic shock.

Albeit, if rheumatic children show signs of hypothyroidism, they exhibit also from time to time signs indicative of hyperthyroidism. Thus, they are highly nervous, are prone to emotional outbursts, bouts of epigastric pain and diarrhea, sweatings, cardiac palpitations, and loss of weight; symptoms presumably resulting from the influence of the thyroid secretion on general metabolism and the adrenal sympathetic system.

We see then that though hypothyroidism may, so to speak, be dominant in rheumatic children, it is not exclusively so. For, as seen on a substrate of hypothyroidism symptoms of hyperthyroidism manifest themselves after a paroxysmal periodic fashion. The explanation presumably is that, given functional inadequacy of the thyroid with consequent endocrine imbalance, the defective gland will, from time to time, strive to correct the disequilibrium. This, as it were, by phases of reactive thyroid hypersecretion, the paroxysmal or periodical incidence of which is determined by similar fluctuations in activity of those factors or conditions tending to inhibit the gland's function and which primarily occasioned the underlying state of hypothyroidism.

Now, as previously observed in Graves's syndrome signs of hypothyroidism and hyperthyroidism may coexist, and I have recorded examples of such possibilities. Moreover, at this juncture when the victim, so to speak, oscillates between the two conditions, cautious thyroid therapy, presumably by stabilization of endocrine equilibrium, has proved beneficial. This renders more intelligible the good effects of thyroid therapy in cases of rheumatic fever refractory to salicylates.

In like fashion in these subthyroidic rheumatic children, tentative thyroid administration often lessens or dissipates their tendency to periodical phases of hyperthyroidism. This, as is revealed by their proneness to disorders of paroxysmal incidence, e. g., tetany, migraine, dead fingers, Raynaud's phenomena, etc.

Would it not be wise, therefore, by way of prophylaxis:

1. Carefully to scan children of rheumatic stock for minor signs of hypothyroidism or more cor-

rectly of hypohyperthyroidism, or thyroid instability.

2. To scan with equal care their parents for signs of hypothyroidism, noting also any tendency to goitre or exophthalmic goitre, either in themselves or other members of their family.

3. In case of refractoriness to salicylates, to suspect thyroid deficiency, and cautiously to invoke, in addition, thyroid therapy.

4. In obstinate or relapsing cases—if residing in a goitrous region—consider removal to a nongoitrous locality.

The predilection displayed by rheumatic children for disorders that are paroxysmal and periodical, is striking. So ingrained, too, is this pathological habit that, when later they present definitely rheumatic manifestations, these also tend to recur in cycles, phases of relative immunity alternating with phases of hypersensibility, the outward reflection of the incessant combat between the rheumatic virus, whatever its nature and the defensive endocrine mechanisms of the organism.

(*To be continued*)

Protein Shock in the Treatment of Rheumatoid Arthritis

J. N. CRUICKSHANK, M.C., M.D., F.R.F.P.S.G.

Glasgow

SPECIFIC AND NONSPECIFIC IMMUNITY

Within recent years a good deal of attention has been directed to a method of treatment known familiarly as protein shock therapy. It has been applied in an experimental manner to the treatment of a great variety of diseased conditions, and even yet its proper value is not fully determined. Among the diseases which have responded more or less successfully to this method of treatment is rheumatoid arthritis, and for this reason the subject is here referred to.

The difficulty—indeed the impossibility—of producing a specific immunity to any infection in the absence of certain knowledge as to the infective agent has long been a great barrier to progress in our treatment of disease by vaccines and similar means. Failure to find a means of increasing the specific immunity naturally turned attention to the possibility of exploiting the nonspecific defensive mechanisms of the body. Certain nonspecific antibodies (in the broad sense of the term) were known to exist in normal individuals, and the idea of increasing the potency of these was obvious. It was known also that the parenteral injection of foreign proteins and similar substances leads to a marked physiological reaction, and this fact was made the basis of various attempts at nonspecific immunization and incidentally conferred on the reaction the name protein shock.

THE PROTEIN SHOCK REACTION

So many factors are involved in the reaction to the injection of foreign protein and other substances of the kind that the actual nature of the reaction is difficult to determine. The more the phenomenon has been studied the more complex has it been found to be. It would be unwise at the present time, therefore, to make any dogmatic statements as to the true nature of protein shock or to attempt to define its relation to either specific immunity or anaphylaxis. Suffice it to say that, so far as our present knowledge goes, such relationships do exist, and that the reaction cannot be fully explained in terms of specific immunity alone.

The actual details of the shock reaction vary considerably according to the nature of the agent employed, the dose, the general health of the subject, and other similar factors. Typically, however, the main features of the reaction are as follows. A short time after the injection has been made all the clinical symptoms of a chill appear. The patient feels ill, and after a preliminary sensation of coldness which may amount to an actual rigor, the temperature rises sharply, reaching its maximum usually within four or five hours, and then falls. Synchronously with the rise in temperature there is an increase in the pulse rate, in the number of leucocytes in the peripheral circulation, and in the blood pressure. These return to normal more or less in sympathy with the temperature curve. As soon as the febrile reaction is established profuse sweating begins and there may be some reduction of blood pressure. A variety of other symptoms may be produced such as headache, nausea, vomiting and nervous excitement. The spleen is sometimes definitely enlarged, and albuminuria is occasionally met with. Apart from these clinical symptoms a number of changes may occur which require special methods for their demonstration. Among these may be mentioned certain changes in the enzymes of the serum to which attention has been drawn by several writers. Petersen, whose monograph on *Protein Therapy and Nonspecific Resistance* contains a detailed account of the whole subject, found that the serum protease, after a preliminary diminution, shows an increase for a period of several days after the reaction. Serum peptidase and ereptase are also increased, and it is suggested that this increased enzyme activity is an important part of the detoxicating mechanism of the body.

A great many substances have been used by various workers as antigens in the production of protein shock. Originally typhoid vaccines were used, and indeed it was during their use in attempts at specific treatment of typhoid infections that many of the earlier observations on nonspecific immunity were made. Mention may be made of other bacterial vaccines, split bacterial vaccines, normal serum, milk, various proteins and their cleavage products such as peptone, enzymes and leucocyte extracts, colloidal metals, such as gold, manganese and silver. The two substances of which I have personal experience are typhoid vaccine and peptone, and the use of these will be described in detail.

TECHNIC OF TREATMENT WITH PROTEIN SHOCK

Intravenous method.—Intravenous injections of Bacillus typhosus vaccine have been used on a considerable scale for the production of protein shock. One reason for the choice of this particular vaccine is the association already referred to between the vaccine treatment of typhoid infections and the early observations on protein shock, as a result of which there accumulated clinical experience of the effects of this antigen. Another reason for its use may be the ease with which antityphoid vaccines are prepared and sterilized. Apart from these considerations there is no reason for using this particular organism. I have noted, however, that in a series of cases in which a Bacillus typhosus vaccine was used, severe herpes of the lips and mouth resulted as a complication, and I was able to trace this to the presence of a particular strain of the bacillus in the mixed typhoid vaccine employed. It would appear, therefore, to be advisable to adhere to a vaccine prepared from strains of Bacillus typhosus which have been tried out and have been found to be suitable for this form of treatment.

The dose of the vaccine may be varied according to the degree of shock desired. To begin with it is well not to exceed one hundred million bacilli, but if the resulting reaction is not sufficiently well marked, the dose may be increased to one hundred and fifty or two hundred millions on subsequent occasions. It is recommended that the vaccine should be diluted with approximately five c. c. of warm (body temperature) normal saline immediately before use, but this does not appear to be essential. The dilution of the vaccine certainly allows of more accurate measurement in a syringe. The actual injection is made with a fine intravenous needle fitted to a small serum syringe, and the most convenient site is usually one of the antecupital veins. The injection should be made slowly, with of course the usual precautions as to asepsis, and as a preliminary to the treatment it is advisable to have the bowels freely moved. Within half an hour or less the reaction should be evident, but its intensity and duration vary with the dose and with the state of the patient. During the reaction the diet should be restricted to fluids and the patient should be kept warm and protected from chill. There is sometimes a good deal of local disturbance in the affected joints but this need give rise to no alarm. After the reaction has subsided there is generally a certain amount of malaise and headache, but these soon clear up, and patients often state that they feel particularly well a day or two after a protein shock.

It is important not to allow too long an interval to elapse between the reactions lest a negative phase develop. Too large a dose of antigen should also be avoided. Either of these may lead to a lowering instead of an increase in the patient's resistance. While the interval between the shocks may be varied according to circumstances, it should be about five to seven days. The total number of doses given depends largely on the degree of improvement which follows in the joints—and also, one may add, upon the docility of the patient!

Intramuscular method.—There are certain obvious objections to the use of the intravenous method of producing the protein shock reaction, and I have found the intramuscular method quite satisfactory. The substance which I have used has been peptone, and the amount given has varied from 0.3 to 0.6 grams. As much as one gram may be required, however. Peptone may be bought from most of the commercial drug houses made up in solution for the treatment of asthma, and the particular preparation which I have used has been a 7.5 per cent. solution prepared by Martindale. This is quite a convenient strength, as five c. c. of the solution is equivalent to 0.325 grams of the solid peptone.

The peptone solution may be prepared, however, by anyone who has the means of sterilizing it. Bacteriological peptone is mixed with normal saline in a mortar and the solution is made up to such a bulk that the strength is equivalent to five or ten per cent. This solution is filtered twice through fine filter paper and distributed among a number of small vaccine bottles or tubes. It is then sterilized by heating to 75° C. to 80° C. for thirty minutes on three successive days. This peptone solution is injected with a fine needle into one of the large-bellied muscles such as the gluteus maximus. One may mention the advisability of withdrawing the piston of the syringe slightly after the needle has entered the muscle so as to make certain, from the absence of any reflux of blood, that the needle is actually in the muscle and not in a bloodvessel. The reaction should be well established within half an hour of the injection.

While it is well to commence with a small dose of 0.3 or 0.4 grams of peptone, the amount may be increased considerably on subsequent occasions. The aim should be to produce a rise of temperature to about 101° F., and there does not seem to be any particular advantage in exceeding this. The number of injections and the length of the intervals between them again depend upon the circumstances of the case. As a general rule one may say that four or five injections at intervals of about a week will be found to be satisfactory.

EFFECTS OF PROTEIN SHOCK IN ARTHRITIS

What then is the value of this protein shock therapy in rheumatoid arthritis? There seems no doubt that in a proportion of cases at least the treatment is followed by definite clinical improvement, but even its most enthusiastic advocates do not claim that the method is to be regarded as a cure. It is generally agreed that other therapeutic measures should be carried out in conjunction with this special treatment. By thus combining ordinary treatment with protein shock it appears to be possible to accelerate recovery of movement in the affected joints in some cases, and in a few cases at least to arrest the disease. Whether such improvements in symptoms or arrest of the disease will prove to be permanent it is too soon to say, but many observers report very encouraging results. It should not be forgotten that since the aim of the treatment is simply to increase the defensive mechanism of the body, it is futile to look for the disappearance of old standing lesions associated with marked structural changes. Lastly, it should be remembered that protein shock therapy has not emerged fully from the experimental stages, and that its use, encouraging though the results appear to be, must be tried out on a much larger scale than has been done hitherto, before its true value can be ascertained.

SUMMARY

1. The intravenous or intramuscular injection of certain foreign substances, particularly proteins and their cleavage products, leads to a marked physiological reaction to which the name protein shock is applied.

2. Since the protein shock reaction results in an increase in the activity of certain parts of the defensive mechanism of the body, it has been introduced as a means of increasing nonspecific immunity in the treatment of infections of obscure origin such as rheumatoid arthritis.

3. The technic of protein shock therapy is discussed and a detailed description is given of, *a*, intravenous treatment with typhoid vaccine, and *b*, intramuscular treatment with peptone.

4. The clinical value and the limitations of the treatment are discussed, and it is concluded that while protein shock therapy has a certain value in the treatment of rheumatoid arthritis—particularly in accelerating clinical improvement—it augments rather than replaces the older methods of treatment. It must be borne in mind that protein therapy is still in the experimental stage.

The Course of Rheumatic Heart Disease

CAREY F. COOMBS, M.D., F.R.C.P.
Bristol, England

The other day I was glancing in desultory fashion at the pages of Watson's *Lectures on the Principles and Practice of Physic*—a delightful book that was in its time the best English textbook of medicine—when my eye lighted on a discussion of the nature and causation of Sydenham's chorea (1). What fixed my attention and induced in my mind a faint sense of humiliation was a remark to the effect that Todd and Begbie, men who were shining lights in the constellation of British medicine in the early Victorian days, had both of them propounded the view that carditis, polyarthritis and chorea were the varying expressions—varying only because they emanate from organs varying in structure and function—of the human body's response to the rheumatic virus. This is the view that most British physicians hold nowadays, but I confess that it was with a mild surprise that I found that it dated from the days of Warburton Begbie and Todd. Perhaps we have advanced a stage or two beyond it; perhaps the truer view is that expressed by Sir Norman Moore in his *Lumleian Lectures* (2), that the carditis is the central fact, with chorea, polyarthritis and so on, for its complications. This balance of alternatives is so much a matter of words and terms that it is hardly worthy of further consideration except in so far as it serves to make clear the sense in which the term rheumatic heart disease, which appears at the head of this paper, is used by me. We are here speaking of an infective disease of the heart, which is likely to coincide with lesions of brain, joints and subcutaneous tissues, very definite in type and playing out its part in strict conformity with certain rules.

Its onset is traceable nearly always to childhood, and adolescence. In about two thirds of over six hundred cases observed by myself, the patient was between the ages of five and fifteen at the time of onset. This is the age at which the body is teaching itself the lessons of immunization against the bacteria by which it is infested. The presence of cardiac disease is first noted under one of four sets of circumstances. The doctor is asked to treat the patient for rheumatic pains or chorea, and looks for and finds signs of carditis: that is the first and largest group. The second group, which is large in proportion to the care which the practitioner concerned is in the habit of devoting to the examination of his patients, consists of children, who, having been noticed to lose flesh and color, or to be wanting in appetite and energy, are found to entertain an active cardiac rheumatism. In the third group attention is first drawn to the presence of a cardiac lesion by symptoms of cardiac inefficiency, dyspnea in particular. Many of these patients have already passed into adult life and in many of these, as in the fourth group—a group of those in whom the signs of cardiac disease are first noted in the course of a general examination such as that of the insurance offices—after inquiry made, the occurrence of some slight rheumatic illness during childhood is recollected.

But, for each and every one of these groups the cardiac lesion may be truly described as rheumatic if it conforms to the rheumatic type, even if there is not the least evidence that the patient has ever had rheumatism or chorea. Often a diagnosis of rheumatic heart disease made on this basis is vindicated by the subsequent appearance of chorea, polyarthritis or subcutaneous nodes; but even when this is not so the diagnosis of cardiac rheumatism is nevertheless to be adhered to if the disease follows the lines of evolution which are characteristic of the rheumatic type of heart disease. In the same way as we are now accustomed to diagnose pulmonary tuberculosis on the general aspect of the case without slavish respect to the results of sputum examination, so also we ought to learn to diagnose cardiac rheumatism without waiting for other rheumatic phenomena.

Now, if we are to follow this principle we must have a clear mental picture of the morbid process by which the lesions of rheumatic heart disease are established. The first basic fact is that it is a pancarditis. All parts of the heart are injured; the myocardium, especially that of the left ventricle, and the mitral valve are always attacked, the pericardium more often than not, the aortic valve in about half, and the tricuspid valve in about a quarter of all cases. The microorganism responsible, a small diplostreptococcus derived in all probability from the alimentary tract, gains access to the cardiac tissues by way of the coronary circulation, so that the lesions which it establishes begin within and about the myocardial

arteries and capillaries (the Aschoff body being one phase of these lesions) and in the subendothelial parts of the valves and pericardium. The myocardial and endothelial cells are attacked by the toxins thus liberated, suffering injuries which vary widely with the amount of the dose of poison inflicted on the heart. These acute changes pass off, if and when the activity of the invasive process dies down, but permanent results remain in the shape of subendothelial and perivascular fibrosis, vascular occlusions, loss of endothelium and deterioration in the quality of the myocardial cells. Each recrudescence of activity adds its quota to all these lesions. Their severity varies widely in degree. At one end of the scale is the case of the child who dies within a few days of the onset because the capacity of the cardiac muscle to do its work has been suddenly destroyed by an overwhelming dose of poison. At the other end is that of the person whose heart has been so quietly and subtly attacked by a long series of minimal doses of infection, that not until adult life is reached are any symptoms or signs of cardiac inefficiency detected. In the former, the clinical picture is that of acute dilatation with ventricular failure; in the latter, that of chronic mitral stenosis. Between these lie every shade of severity, every conceivable combination of acute and chronic lesion, every kind of pancardial damage.

Now, a followup of over six hundred cases of rheumatic heart disease, the results of which have been fully published in a book on *Rheumatic Heart Disease* (3), recently published, disclosed certain facts. First, the average age at death in this clinical series, as well as in a series of cases examined post mortem at the Bristol General Hospital, was twenty-eight years. Second, there was in each of these series only one year between the ages of seven and fifty which failed to claim a single victim. Thirdly, in both series over thirty per cent. of the fatalities occurred during the second decade of life; that is to say, taking the average age of onset as ten, it is the first decade after onset that is the deadliest. The reason for this is not difficult to perceive, for it is during the first years of infection that the infective process is most active. The more rheumatic microorganisms there are in the heart tissues at any one moment, or within a given time, the more likely is the heart to be defeated. This simple, yet farreaching principle of prognosis, is strikingly illustrated by facts relative to the influence which the kind of onset has on the duration of life in rheumatic heart disease. Of those rheumatic children who are first seen by reason of chorea, only one in thirty dies of heart disease in the first decade. Of those whose first symptoms are articular, one fifth die in the first decade; of those who are first seen for the carditis itself, over a quarter; and of those who have subcutaneous nodes at the first visit, fifty per cent. fail to survive for ten years. What is the meaning of this? It is very simple. It takes a minimum dose of infection to cause chorea, the brain being so sensitive an indicator of infection, and a maximum dose to cause so gross a reaction as a palpable node in the subcutaneous tissues; while the heart and the joints lie between these extremes. In other words, the prognosis is worse in those patients who show signs of systemic saturation with the rheumatic infection, just as we have already seen it to be worse in proportion to the degree of saturation of the cardiac tissues by that infection. An interesting aspect of this latter fact is to be found in the gravity which the detection of pericardial friction lends to the prognosis of a case of rheumatic carditis. Children whose signs of cardiac rheumatism include those of pericarditis do worse than the others—a generalization to which, I suppose, every physician of experience would agree—not because there is anything essentially or intrinsically lethal about an inflamed pericardium, but because it is only when the heart is infected through and through that the pericardium is inflamed. The more organisms there are in the wall of the heart, the likelier are they to penetrate into the pericardial sac and there to arouse a reaction that can be detected clinically.

We must be content with this brief summary of some of the evidence in support of the view that since cardiac rheumatism is the result of saturation of the tissues of the whole heart by the rheumatic cocci, the greater the degree of that saturation the more rapid the progress of the disease. We have next to glance at another equally obvious deduction. If it is the whole heart that is attacked by this infection, the muscular lesions will matter most because the muscular functions are the chief functions of the heart, the purpose for which it exists and for the furtherance of which all its parts are adapted.

The most obvious exemplification of this truth is to be found in the fact already stated, that it is the first decade of the infection that is the deadliest. Deaths at this period are of the kind associated with acute dilatation of the heart, that is to say with acute ventricular failure; and this in turn is but an expression of ventricular infection. That this is so is proved by the constancy with which the characteristic inflammatory foci are found in the ventricular walls, and by the absence—at this stage—of any lesions other than muscular lesions, that could conceivably cause a fatal decline in the contractile power of the heart. How could such a catastrophe possibly result from swelling and fibrosis of the valves or from fibrinous exudation in the pericardial sac causing its obliteration? Such lesions as these must not only be themselves extreme in degree in order to bring about the failure of an organ, the amplitude of whose reserve force is proverbial; they must also have been established long enough to have depreciated the value of the muscle cells. Now, neither of these conditions has been satisfied in the first decade after infection, and it is therefore to the muscular lesions that we must turn if we are to account for the high mortality of that decade.

It must be admitted that if we turn to the other end of the chapter, to those decades to which the "lucky" patients survive, we come upon a state of affairs in which the part played by direct action of the virus on the cardiac muscle is not so obvious. The clinical picture that we find here is that of a patient with the signs of mitral obstruction to which have been added the phenomena of auricular failure. There is little in this to suggest that active infection of the heart has done the mischief. But indeed, it is a fact that this failure of the auricle is not usually a direct result of infective damage to its muscle. Twelve hearts from patients with rheumatic heart

disease and auricular fibrillation were submitted by me to a thorough examination, including serial sections of the sinuauricular node, and many sections of other blocks from various parts of the auricular walls, and in only one of these was there evidence of an acute inflammatory basis for the auricular failure. In the remainder the changes in the auricular walls were obviously degenerative, due presumably to long continued overstrain on the one hand, and coronary stasis on the other, both of them the result of the narrowing with obstruction at the mitral orifice that is so constant a feature of the survival phase of cardiac rheumatism. This auricular failure, then, that is so often seen in the last years of the cardio-rheumatic life, is due only indirectly to inflammatory processes, yet the patients who survive the onset of that failure longest are those whose hearts are least affected in other ways; in particular those who have least enlargement of the ventricles. It is not surprising that this should be the case. The chief menace to life implied in failure of the auricular functions lies in its influence on the work of the ventricles. The rapid irregular stimulation of the ventricles, that is the cardinal feature of auricular failure, spells ruin to the ventricular efficiency, since it reduces the diastolic rest of the heart to a dangerously small fraction of the normal. If the walls of the ventricles are already carrying on with difficulty, this further burden of rapid irregular stimulation will be unendurable, and failure must ensue. Now, lesions of the ventricular muscle in cardiac rheumatism are in the main due to the direct action of the rheumatic infection on that muscle. Ventricular muscle that was gravely injured in the first decade of the disease will, at the end of the second decade, be less able to endure the extra strain put on it by auricular failure than that which has suffered less severely. Once more, therefore, we come back to the conclusion that the lesions of the cardiac muscle that are directly traceable to active infection, are more hurtful to cardiac efficiency than any other of the component factors of rheumatic heart disease.

There is another aspect of the survival phase of cardiac rheumatism that is worthy of comment. Often mitral stenosis is looked upon as the result of an endocarditis which happened once for all in childhood and started a fibrosis which progressed thereafter by its own momentum. That this does not represent the whole truth is proved by three facts. First, the more carefully we watch our patients with mitral stenosis, the more likely we are to find brief periods of fever and other signs of infective activity. Second, autopsy shows that even where no such signs are present in life, evidences of active inflammation of the mitral cusps can often be seen with the naked eye. Third, mitral cusps that present no such naked eye changes can be shown by the use of the microscope to be the seat of an active inflammatory reaction. That valvular fibrosis which plays so large a part in bringing about breakdown in the last phases of cardiac rheumatism is itself the outcome of an active inflammatory process which is in all probability due to persistent or often repeated infection of the valvular tissues.

I submit, then, that the course of rheumatic heart disease is, from start to finish, that of an infective process. In this respect it is comparable to the course of such diseases as pulmonary tuberculosis or cerebrospinal syphilis. Experience has taught us that our hope of abolishing these diseases lies chiefly in prevention. Treatment may retard and even arrest their progress, but it cannot make the injured tissues whole again. What is true of these diseases, is true also of rheumatic heart disease. If we are to save humanity from the distress and waste which this disease inflicts, it must be by a policy of prevention, directed and informed by a knowledge, clearer and more accurate than that which we possess at present, of the causal microorganism and the conditions under which it flourishes.

Arthritis and Infection of the Digestive Tract

N. MUTCH, M.A., M.D. Cantab., F.R.C.P. Lond.
London

This communication is based upon an analysis of two hundred cases personally investigated from many different walks of life. Gout, venereal or tuberculous disease of the joints, and all cases of monarthritis have been excluded, but no other selection has been exercised, and with these exceptions the cases may be regarded as consecutive.

Areas of infection in the alimentary tract are often multiple and can be divided roughly into an upper zone which includes the mouth and throat, and a lower one which comprises the bowel and its appendages. In the present series, active sepsis was present in the throat and nose in thirty-four per cent. of the cases, and around the teeth in fifty-two per cent., while infective streptococci were recovered from the feces of eighty-four per cent. The great importance of the lower zone has been shown clearly by Sir Arbuthnot Lane and is well demonstrated by the two following cases:

CASE I.—In this instance absolute cure followed the removal of the infected colon, although areas of chronic infection in the tonsils were left untreated. M. H., a woman of twenty-eight, had suffered from severe constipation since infancy and from rheumatic arthritis for fifteen years. All her joints were affected. Her colon was removed in 1913 and liquid paraffin taken as a routine measure afterwards. No other treatment of any kind was employed. She became free from pain after a few days and has never had any more pain or swelling in her joints

up to the present date. She has gained four and a half stone in weight, can bathe in the sea with impunity, and leads an active life with a normal feeling of vigorous wellbeing.

Case II.—This patient's arthritis was cured by colectomy although he had pyorrhea alveolaris which was left untreated. H. M., a boy of thirteen, had been constipated for many years and had had rheumatoid arthritis for fifteen months affecting knees, ankles, elbows and jaw. There were pyorrhea pockets between the gums and teeth and radiograms showed involvement of the periodontal membrane. Colectomy was performed and the pain left his joints. During the next few months a flexion contracture of the elbow straightened itself without any manipulations, and now, five years later, he is a well-developed young man following a laborious occupation and with no trace of his former joint trouble.

COMPARISON OF FORMS OF INFECTION

Although much infection takes place from the tonsils and jaws, invasion from the bowel is of a much more serious nature. Chronic arthritis often commences many years after the extraction of all the teeth. This had occurred in fifteen per cent. of the present cases, the period which had elapsed between the extractions and the onset of arthritis varying from two to twenty years and the average time being eleven years. In these patients invasion of the joints must have taken place from some other mucosal focus. Another sixteen per cent. had had total extractions done during the course of the arthritis and yet continued to have outbursts of arthritis with the involvement of fresh joints. Almost all the extractions had been done for gross septic conditions. Critical analysis of the throat histories shows a similar state of affairs. Four per cent. of the patients had had their tonsils enucleated many years before the onset of arthritis, and another five per cent. had received no benefit from enucleation carried out during the course of the disease. The remaining ninety-one per cent. still possessed their tonsils. If this inquiry is taken one step further it is easy to find patients with continued arthritis who are both edentulous and devoid of tonsillar tissue. The explanation of the failure in the treatment of these patients lies in the infection which was taking place from the lower zones in the bowel and which had been neglected after the cleansing of the mouth.

INFECTIONS OF THE BOWEL

The lower zones of infection can be divided into two anatomical groups. In the first group are localized infections. Mechanical agents, such as hard feces, obstructions, stasis, ptosis, and distention with gas produce loci of depressed resistance through attrition, local poisoning of the mucosa, and interference with the flow of blood and lymph. In these places infective bacteria establish areas of chronic infection in the wall of the bowel. Stercoral ulcers, diverticulitis, ulcerated piles, cholecystitis and chronic appendicitis are common examples of this type of infection. In the second group there is a diffuse infection which sometimes involves the whole intestine from duodenum to rectum, and may or may not be associated with circumscribed zones of special activity such as have been placed in the first group.

Most of the infections are streptococcal, but a few, four per cent. in the present series, are staphylococcal.

Staphylococcal infections.—The two following cases are typical examples:

Case III.—D. W., a boy aged five, had suffered from constipation since birth and from Still's disease for two years. His hips, knees, ankles, wrists and elbows were seriously involved. He had much intermittent pyrexia with rigors. Blood cultures yielded a pure growth of Staphylococcus citreus. Cultures taken from his ileum during a laparotomy also gave a growth of the same organism.

Case IV.—F. P., a woman of twenty-seven, had for three years suffered from rheumatoid arthritis of the fingers, wrists, knees, and spine. Stasis occurred in her ileum and colon. At laparotomy her mesenteric glands were seen to be acutely enlarged. Cultures from them gave a pure growth of Staphylococcus aureus and similar organisms were obtained from the contents of the ileum.

RATIO OF STREPTOCOCCUS LONGUS TO BACILLUS COLI

Site	*Averages of 21 serial analyses*	*Averages of all analyses*
Duodenum	100.0	100.0
Jejunum	100.0	100.0
Upper ileum	80.20	83.17
Lowest ileum	46.54	41.59
Cecum	24.76	18.82
Pelvic colon and feces	3.97	14.86

Streptococcal infections.—In this widely distributed group are included infections by many different types of streptococcus, and only six per cent. of the present series were hemolytic. In about one third of the cases abnormal forms of the colon bacillus of the nonlactose fermenting or late lactose fermenting varieties were found in association with the cocci. In the diffuse infections the streptococci are distributed along the alimentary tract in a definite pattern. In the pelvic colon they are much less numerous than the colon bacillus. In the ileocecal region they become more conspicuous and at the higher levels are usually present in pure culture. This distribution is illustrated in the table. In the second column are given the averages of analyses carried out on twenty-one patients from each of whom serial cultures were made at several levels at laparotomy. The pattern was the same in each of the twenty-one cases. In the third column are given the averages of analyses made on a much larger number of patients, including many cases in which an analysis was made at one level only. The same pattern can be seen in each series. Streptococci predominate in the small bowel and the colon bacillus in the large bowel. The precise level at which transition takes place from streptococcus to Bacillus coli dominance varies in different patients, because of variations in the chemical nature of the contents of the bowel determined by differences in diet, peristalsis, and ferment efficiency. The point of transition is usually in the ileocecal region, but may be on either side of the ileocecal valve.

MORBID CONDITIONS UNDERLYING THESE INFECTIONS

Chronic infections do not arise in the normal alimentary tract. Derangements, often of severe degree, were traced in more than ninety per cent. of the present series.

Stagnation is almost universal. Three quarters of the patients had suffered from constipation for many years prior to the onset of arthritis and in almost half of these cases the constipation had been severe. As measured by means of an opaque meal and x rays stasis was found as commonly in the small bowel as in the large. In the colon it occurred in eighty-nine per cent. of cases, the average time taken for the evacuation of the greater part of the meal in these cases being more than three days, while in some instances a week was required. In the ileum stasis was found in ninety per cent. of cases. In these the average time required for the ileum to empty, after all the barium had left the stomach, was eight hours, whereas under normal circumstances only three and a half or four hours are needed. Stasis was not so common in the stomach and only occurred in one third of the cases. The average time taken for the meal to pass through the stomach was eight hours, or twice the normal time. In many of the patients repeated overloading of the colon during a period of years had led to compensatory hypertrophy with elongation. Three quarters of the patients had long redundant loops of pelvic colon and in two thirds the transverse colon was doubled in length and hung in a tortuous festoon across the abdomen. In many patients there had developed secondary obstructions which aggravated the primary stasis. One half of them had a kink in the last coil of ileum. One third had a very acute splenic flexure in the erect posture and as many as ninety per cent. had a last kink in the pelvic colon. The appendix was examined at all laparotomies and whenever the opaque meal entered and displayed its shadow on the fluorescent screen it was abnormal in three quarters of these cases. Sometimes it was the seat of chronic inflammation, but more frequently it was fixed to the posterior abdominal wall and acted mechanically by interfering with the passage of the food through the last coil of ileum.

Ptosis had occurred with great frequency to the hindrance of peristalsis and the free flow of blood and lymph. For the purposes of this description only outstanding examples in which the ptosis was so severe as to be beyond all dispute have been noted. In fifty-one cases the greater curvature of the stomach was within an inch of the symphysis pubis in the erect posture, in 133 cases the cecum was deep in the pelvis. In an equal number the hepatic flexure was in the right iliac fossa and in about the same proportion of cases the transverse colon fell to the level of the symphysis pubis.

Ferment action was commonly defective and digestion slow, so that much unassimilated food found its way into the large bowel where it formed a suitable nidus for bacterial activity. The production of an excess of gas affords the most direct evidence of such activity and 130 of the patients complained of this undue flatus in the colon. A similar proportion complained of gastric symptoms which were of many different kinds and varied in severity from heartburn and nausea to vomiting and acute epigastric pain after meals. As a group these symptoms indicate the great frequency with which errors of digestion in the stomach and duodenum occur in arthritic patients.

Apart from bacteriological analyses much direct evidence of infection of the colon was forthcoming. Intermittent looseness of the bowels, short attacks of severe diarrhea, and the repeated passage of mucus were of common occurrence, while in a small minority of cases persistent diarrhea replaced the more usual constipation. A history of one or other of those varieties of diarrhea was given by sixty-seven per cent. of the patients.

In certain cases there were extensive lesions of other kinds in the alimentary tract. Chronic gastric ulcers were seen in seventeen per cent. of those cases upon whom high laparotomies were performed and histories of recent severe hematemesis were given by two per cent. of the other patients. Gallstones were found in eleven per cent. of high laparotomies and typical histories of gallstone colic were given by three per cent. of the remaining patients.

MASKED STASIS AND HIDDEN SEPSIS

Study of this series has shown again and again that stasis and sepsis can exist in the intestine and yet not be manifest without investigation. The bowels may act every day in spite of serious delay in the colon. The residues from the meals of the preceding twenty-four hours are not evacuated, but are stored up by such patients and passed out at the forty-eighth or seventy-second hour, as the case may be. The colon always contains the accumulated débris of two or three days' meals. In other cases the latent stasis is in the ileum, where the food may be retained for twice the normal time before it is passed into the cecum. Such a delay does not of necessity interfere with the regularity of defecation or give rise to discomfort in the abdomen. Masked stasis of these types is at once brought to light by systematic radiography, but cannot be detected readily in any other way. Sepsis in the bowel is just as frequently masked. Even extensive invasion of the bowel by infective bacteria such as streptococci does not always produce diarrhea or any other sign of irritation. The true nature of these cases can only be detected by serological tests and the examination of cultures of the stools. Serious streptococcal infection of the ileocecal region sometimes occurs even when the flora of the feces appears to be normal. Such cases have frequently been investigated at laparotomy when samples of chyme could be obtained from the small intestine. In other cases they can be detected by giving the patient an ounce of lactose, a dram of magnesium sulphate, and the juice of a lemon in water before breakfast on three consecutive mornings and examining the stools which are passed on the third day. The lactose reaches the colon and promotes the growth of streptococci which are hurried onwards so rapidly by the magnesium sulphate that they can be recovered from the stools.

In brief, it can be stated that stasis often occurs in the colon although there is a daily evacuation; stasis often occurs in the ileum, even when the patient does not refer any symptoms to the alimentary tract; streptococcal infections are often present in the bowel, although there are no symptoms of irritation of the colon, and extensive infection of the ileocecal region does not always lead to the excretion of living streptococci in the feces.

RESULTS OF TREATMENT

The condition of the alimentary tract dominates the outlook in rheumatoid and osteoarthritis. The general scheme employed in the treatment of the present series of cases has been as follows: The entire alimentary tract was surveyed carefully in each case and an estimate formed of the relative degrees of septic absorption occurring at the various levels. The more accessible areas of infection in the jaws, throat, and intestines were treated surgically and all the disorders of the digestive tract which had encouraged the development of chronic infection were dealt with. Autogenous vaccines proved of great value when used to supplement these measures. They were prepared from infective bacteria of all the principal zones of sepsis. Streptococci obtained from different foci in the same patient usually vary in their cultural characters, and each strain was included in the vaccine. Chronic infection frequently damages the thyroid gland. In the present series minor forms of subthyroidism were common, while well defined myxedema or goitres of considerable size were seen in fourteen per cent. of cases. There is intimate association between immunity reactions and the functions of the thyroid gland. The dry extract of the thyroid was given in all such cases with great benefit to the joints. Accurate diagnosis aided by radiography and bacteriology, makes radical treatment and cure possible. In the present series of cases, which have been followed for varying periods up to nine years, eighty-nine per cent. show great improvement or complete arrest. Of the failures one quarter had received very partial treatment only and could not be inoculated with vaccines. If it were possible to exclude those cases in which circumstances such as age, temperament and position in life prevented the full use of radical methods the results would have been still more encouraging.

Diet in Rheumatism

ADAM H. WRIGHT, B.A., M.D., M.R.C.S., Eng.
Toronto

We are sometimes asked, "Does meat, especially red meat, cause rheumatism?" If we considered the question in the sense generally intended by the inquirer, our answer would be "No." The nitrogenous foods taken in moderation are useful; when taken in excess, they putrify and cause the intestinal toxemia which produces baneful effects on the whole system. A properly balanced diet is our most important safeguard against various diseases of which one is rheumatism. So far as possible, variety should be unrestricted, balance carefully preserved, and quantity distinctly limited.

The directions generally given as to diet in acute rheumatism are simple, brief, and perhaps, narrow. We are told by many to give milk, farinaceous foods and suitable drinks. "Nothing but milk should be given until the temperature has been below 99° for twenty-four hours" (Latham, England). "Only milk and farinaceous food" (Friedenwald, United States).

We are told by Einhorn that in former times, and up to seventy-five years ago, the teaching of Hippocrates prevailed; and the custom was to withhold nourishment (including milk) from those having any form of continued fever, and give them only weak tea, barley water, and similar substances up to the time of convalescence.

Then came the great physician, Graves, who said the starvation method was wrong, and used instead nourishing food, especially milk in large quantities. Before long Graves's views were generally accepted.

To a considerable extent, at least, we agree as to the value of milk; but we differ regarding some details. It is frequently, if not usually, termed "a liquid food which is easily digested." Soon after it reaches the stomach, however, it becomes a solid food which is more or less difficult of digestion. Chalmers Watson of Edinburgh tells us a solid curd is formed in the stomach by the ferment rennin and the acid of the gastric juice. There is also a process termed clotting, which he says must be distinguished from curdling. The clot consists of the solidified casein with fat entangled in its meshes. This clot becomes "more tough and less easily digested" than the curd lump. "In enfeebled states of the digestive apparatus a hard indigestible mass forms which proves an irritant to the whole intestinal canal, and sometimes is recognizable unchanged in the feces."

Rheumatic fever has two serious aspects beyond all other fevers. It produces profound anemia, and also, as a frequent sequel, organic disease of the heart. We should guard against these in our treatment, especially dietetic and medicinal. There is no other form of fever in which a carefully selected diet is more important, and yet there is none in which the directions generally given are so meagre.

Milk is an excellent food in both health and sickness, but as an exclusive diet suits very few, if any. I know a couple between the ages of forty and fifty, both strong and healthy; the husband loves milk and can take four glasses a day with comfort, the wife hates it and a half glass causes discomfort. Would you try to compel this woman to drink two quarts of milk a day if she contracted rheumatic fever? But take two persons not so far apart, each having a limited capacity for milk. With such it is often difficult to decide as to amounts which should be prescribed. When you give solid food, say bread and butter, a man may stop eating when hunger has ceased, but when you give liquid milk, thirst may be the predominant factor, and the patient cannot tell when he has taken enough for the food needs of the body.

We have also to consider changed conditions in disease, especially in the digestive apparatus. Supposing one can take and digest three or four pints

of milk a day when well, we do not know that he can assimilate that amount when sick.

Another feature may now be considered. We are not asked to discuss medical treatment, but we cannot altogether ignore it. If any medicine produces ill effects, it may compel us to modify our dietary. For instance, sodium salicylate reduces temperature and relieves pain in rheumatic fever, and for these reasons is administered, but we find that its effects are in some respects noxious. It invades important nerve centres, causes ringing in the ears with sometimes deafness, and disorders of vision; irritates the kidneys, vitiates the blood, has a bad effect on the heart, nearly always nauseates, and not infrequently puts the stomach quite out of commission.

Osler expressed the opinion that the salicyl compounds relieved pain, but did not influence the duration of the disease or prevent cardiac complications. Relapses are more frequent than in any other method of treatment. I quite agree with Osler, and have administered no salicylates for thirty years. It is only fair to state, however, that many do not concur. Burney Yeo, as good if not a better therapeutist than Osler, believed the "treatment by salicylates has proved more efficacious than any other."

It appears to me that the pain reducers in rheumatism which interfere least with digestion are chloral and morphine, especially in combination.

Yeo strongly recommended the milk diet: three to four pints in twenty-four hours with large amount of water, lemonade, etc., making altogether one hundred and fifty ounces of liquid a day. When milk disagreed he gave whey.

A vegetarian diet has been recommended, but it is of little use for building up, and is worth little or nothing for the anemia and weak heart of rheumatism. Milk is the best food for infants and young children. To a less extent it suits the aged. In the House of Industry, Toronto, old people are occasionally given milk alone for limited periods. The inmates, knowing this, usually ask for the milk when they get off color, and get it as long as they want it. They enjoy it and derive much benefit, but grow tired of it in six or seven days, and then, at their own request, return to their ordinary diet. When I first learned this years ago I thought it odd that all or nearly all should want the exclusive diet for the same definite time—six or seven days. I have also noticed that in the continued fevers, especially rheumatic, patients who took milk willingly in the first week grew tired of it in the second.

After graduating I for some years prescribed the exclusive milk diet in typhoid and rheumatic fevers and also in the toxemia of pregnancy. After careful observation I acquired the opinion that milk was not always easily digestible, that its influence for good in these diseases was either slight or nonexistent.

As mentioned before, variety, quantity and balance are important in all diets but especially in that for inflammatory rheumatism. Milk contains a greater variety of nutriment than any other food or class of foods. Within proper limits it is serviceable; excess may make it harmful. Cream, butter, cheese, junket, etc., may be considered by themselves. As to limitations, we should name one to two instead of three to four pints as the maximum a day. As to substitutes, we rely mainly on buttermilk or occasionally some of the artificially soured milks. We have discarded whey because it has very little nutrient value on account of the removal of the fat and casein. As to ordinary beverages, one could name a score or more. Let the patient choose for himself as far as possible.

From milk we turn to starchy foods, without trying, however, to disassociate these from other sorts. We want to make as much variety as possible. We have to consider, for instance, bread and milk, bread and butter, with perhaps jam or cooked fruits, mixtures of barley water and other cereal waters with milk; combinations of porridge, boiled rice, and simple puddings, etc., with milk. When ringing in the changes we can easily run up into the hundreds. If some of them are solid or semisolid, no harm. They are generally quite as palatable and digestible as milk even when diluted, often more so.

There is not much to say about vegetables, although they are, of course, an important element in our ordinary food supply. Most of them may be used, especially in the later stages of rheumatism. We may consider the potato a vegetable, and we have only to say that it is easy of digestion and a good food. There is no reason why it should not have its place in a rheumatism dietary. Of other vegetables we find that many are rather coarse fibred, and, being bulky, are apt to cause indigestion, or rather seriously affect a digestion already to some extent disordered.

Fruits mostly cooked may be used to a considerable extent. Among those may be mentioned baked apples, apple sauce, peaches placed in boiling water with the skins on, and nearly all sorts of preserves, jams, and similar substances. Almost the only fruit recommended in the raw state is the grape, rejecting, of course, the skin and pips.

There is considerable objection to the use of meats, and without any extended discussion I shall simply give my own views. Meat extracts and broths may be given at any stage, and after six or seven days if not earlier small quantities of roast, broiled, or boiled meats of any sort may be given with safety, but, in order to keep out of the danger zone only small quantities should be given, and at only one meal of the day.

In rare cases alcohol may be useful as a food where there is hyperpyrexia and the patient is greatly exhausted. In saying this we are referring to it only as a food. Its virtue in these cases lies in the fact that it is absorbed rapidly. Because of its speedy action we employ it sometimes in serious cases of emergency which arise in the various fevers. During such a crisis a little alcohol may be given, and perhaps the best sort available for the purpose is ordinary whiskey, but we have to remember that alcohol is a poison, and little of it goes a long way in that direction when the vital powers are at a low ebb. It is difficult to state a definite amount, but we should say that not more than half an ounce of whiskey added to four ounces of water should be given at any one time, and as the patient is sipping this small amount the effect should be carefully watched. But when giving alcohol as food keep

in mind its potency as a medicine. When there is serious heart weakness stimulation may soon give place to depression.

In health one may enjoy a meal of roast mutton, potatoes, cabbage and custard pie. But if it were repeated for five successive days one might ask for a change. With a digestive machinery thrown out of gear the rheumatic patient does not want any food very much, but would like changes, and probably lots of them. With hundreds of sorts at hand surely you can give him variety.

Restriction brings greater difficulties which require careful consideration and good judgment. Aim at giving sufficient for hunger without causing satiety. If the patient has no hunger and refuses all solid or semisolid food give him plenty of water in some form—a little weak tea if you like. Small quantities of barley water, oatmeal water, toast water may be tried occasionally. If, in case of extreme anorexia, you decide to try milk endeavor to prevent the formation of the curd lump or the fat-casein clot: dilute well say one part milk to two of the diluent which may be plain water, or soda potash, seltzer or salutaries. This means milk one in three while the dilution before recommended was half and half. In many cases with a rebellious stomach plain water (say a gallon in twenty-four hours) may be taken readily, if not greedily, with satisfactory results.

Do not make any list of avoids. There is no food which when used correctly will produce rheumatism. But, one may ask, would you recommend roast goose, pickled cabbage, mushrooms, Brazil nuts, etc.? Probably not, but no one can say that any of them would be always harmful. It would be better probably to select foods in their order of digestibility so far as you can judge, and your list will be so long that you are not likely to reach the goose or cabbage in forty or twice forty days. Therefore do not waste much time in deciding on the foods to prohibit, but always avoid anything in the way of food that has previously disagreed whether before or during the illness. Among the most frequent of these are perhaps, eggs, strawberries, roast veal, tomatoes, and cheese, but there are many others.

Balance, always complex, becomes more so as we increase variety. The following dietary will indicate to some extent the lines we should follow. It is necessarily incomplete, and should be changed and enlarged as considered advisable by doctor and nurse. Increase the number of foods for the different meals if you like, but select carefully for each meal, change from day to day, but measure carefully. For the first two weeks especially too much is worse than too little.

BREAKFAST 7 TO 8 O'CLOCK

Water; one glass of diluted milk; cereal, wheat, oats, corn or barley (three to four ounces or half a small helping) and milk, or bread or toast and butter with cooked fruit or jam, a small cup of coffee or a half cup of orange juice, or half grape fruit. As at all meals give patient water first, as much as he cares to drink, then the milk. If he prefers not to drink the full glass of milk, let him take only as much as he likes. If he drinks the full glass, and would like another at the close of the meal, give it to him. But never urge him to take at any meal more than he wishes, whether it be an ounce, a gill or a pint. We also think no milk should be given between meals. The stomach gets no real rest—not even partial relaxation—when milk is taken every two hours.

LUNCHEON 11 TO 12 O'CLOCK

Water; glass diluted milk, vegetable soup, four ounces, or meat broth, four ounces, or meat jelly, one teaspoonful, half a small helping of spinach or two stalks of asparagus, or milk toast, or half artichoke, or carrot or turnip, or parsnip or baked apple or stewed rhubarb or soft boiled or poached egg (half to begin with).

DINNER 4 TO 5 O'CLOCK

Water; glass diluted milk or buttermilk, or bread and milk (six ounces milk and half slice stale bread); meat broth three to four ounces or vegetable soup three to four ounces, or butcher's meat, or chicken, or fish; beets or squash, or cooked tomatoes; boiled rice and milk tapioca or bread pudding, with milk and a little sugar if desired.

Give the soup or broth at one of these meals (luncheon and dinner) and the meat or fish at the other.

SUPPER OR FOURTH MEAL 7 TO 8 O'CLOCK

Water; milk or bread and butter, or corn cake, or oat cake, or graham gem, or zwieback, or wheat rusk or abernethy cookie; maple syrup, or preserved or cooked fruit, or honey.

Four meals in the day are recommended only in exceptional cases and for limited periods, the fourth to be discontinued as soon as possible.

This dietary may be to some extent misleading partly because it is intended to cover all stages of rheumatism from acute to chronic. To prevent misunderstanding, the following is recommended for the first week of acute inflammatory rheumatism.

FIRST WEEK

First meal—Water; diluted milk, barley water, or rice water, or oatmeal water.

Second meal.—Water, bread and milk, or bread and butter, or meat broth.

Third meal.—Water, diluted milk or buttermilk, tapioca or sago or bread pudding, or milk toast.

Give water at the commencement of every meal, and at any other time during the twenty-four hours up to two to three quarts.

It is hoped the water at the meals will quench the thirst, while the milk and cereal water will satisfy the hunger.

After the water give a full glass of the diluted milk or as much of it as he wants. At the close of the meal give a second glass if it is desired. Aim at giving up to one to two pints a day, but never in any case more than he desires.

During the first and second weeks Nature indicates through increased thirst that the body needs more than the usual amount of water, and through decreased hunger that the digestive system can utilize comparatively little food for the time being, whether liquid, semisolid or solid.

Historical Medicine

Herodicus and His Hygiene as Viewed by Hippocrates and Plato

JONATHAN WRIGHT, M.D.

Pleasantville, N. Y.

The aspirations of this title are more accentuated in alliteration than in any hopes I have of making head against the wild exaggerations of college athleticism. I hope, however, there can be worked into the story, in the place of much moralizing, accounts not totally devoid of interest and suggestion.

The confusion about Herodicus and Prodicus is a small embarrassment in the history of Hellenic medicine over which most if not all commentators have stumbled ever since Galen. It is a small thing but it is so perplexing it is almost amusing. On the whole there is little instruction to be derived from the personal side of it except the small light it throws on Galen as the source of our knowledge of ancient medicine. In the works of Plato and of Hippocrates themselves there is no question at all who is Herodicus and who Prodicus. The Herodicus of *The Republic* is "the inferior sort of a doctor," a keeper of a sanitarium of some sort, a trainer of athletes, himself dragging out a miserable existence as a valetudinarian. Before the time of Herodicus the guild of Æsculapius, according to Plato, did not practise our present system of medicine but one "which may be said to educate diseases, but Herodicus was a trainer," etc. In the Hippocratic Corpus he is a practitioner who destroys his fever patients with gymnastics.

AN UNKNOWN PUGILIST
Rome, National Museum

In the *Protagoras* he is spoken of as "now of Selymbria and formerly of Megara." In the *Phædrus* Herodicus is spoken of as recommending his patients to walk to Megara and back, seventy miles, but in the *Gorgias* there is an Herodicus, a physician, spoken of as the brother of Gorgias of Leontinum in Sicily. It is difficult to identify this Herodicus with the Herodicus "of Selymbria," which was in Thrace, "formerly of Megara, 210 stadia northwest of Athens," but not impossible. The brother of Gorgias may have come to Megara or Athens and then gone to Selymbria in Thrace. Such peregrinations were ascribed to Hippocrates II, "him of Cos."

The *VI Epidemics* of Hippocrates, it is agreed by Galen, Littré and Adams, was written by a son or son in law of the Great Hippocrates, but this opinion seems based on the mention of an Herodicus who gave his fever patients too much gymnastics. They identify this Herodicus, as I have intimated, with the Herodicus attacked by Plato for exercise theories and for his folly in keeping chronic sick people alive by a regimen of diet.

Now let us turn to Pliny, the elder. There is no Herodicus mentioned by him, at least none noted in the careful and copious index of Silleck, but there is a Prodicus mentioned as being born at Selymbria, a disciple of Hippocrates, using medicines by inunction, who invented diet in the treatment of disease. It is difficult not to see in this Prodicus of Pliny, who wrote in the first century A.D., the Herodicus and not the Prodicus of Plato's dialogues. It seems probably we owe to Soranus whose chronology is uncertain, the statement that Prodicus was an instructor of Hippocrates. He is the author of a life of Hippocrates, a fragment of which we have. He probably wrote after Pliny and very possibly much later. This may have been a mistake or he may have been both a pupil of Hippocrates and one who interested him in gymnastics as an aid to treatment. We struggle along thus far eluding difficulties with difficult hypotheses, but when we reach Galen our entanglements thicken. He calls this Herodicus, as Pliny does, Prodicus, but he knew it was not in accord with the text of Plato. He says, with a singular blindness to the question, it is of no consequence whether we call him Prodicus or Herodicus. It is to be presumed that elsewhere he is speaking of the same person when he says Prodicus wrote a book on Medicine or Nature. "Plato exhibits profusely the inventions attributed to this man," a saying which makes us suspect he confounds him with Prodicus of Ceos, sophist and philosopher. Galen quotes from the medical author the advocacy of the use of milk in phthisis and mentions his opinion on the subject of phlegm. It is Prodicus he names in the *Methodi Medendi* and his commentary on the *Aliment* by Hippocrates but it is Herodicus he mentions in the same connection as to a milk diet as in the *Methodi Medendi* in another book, *De Macore*. So it is evidently the same person.

In order that we may see it does make a great deal

of difference in the history of medicine whether the person is called Herodicus or Prodicus, in connection with a personage of the Platonic dialogue, it is well to be reminded how famous was the Prodicus in them.

Prodicus of Ceos was a teacher of the youth in Athens, a philosopher who had Socrates as a pupil, though in one of his discourses the latter says he was too poor to pay him the fifty drachmæ which was his price for instruction. Aristophanes introduced him in some of his dramas, though he is not so severe on him as on Socrates. This Prodicus, the great philosopher, the celebrated sophist, too was not robust and something of an invalid, but in Plato's dialogues he is very differently and much more often mentioned than Herodicus. It was quite natural for Pliny or a copyist of Pliny to write or to mistake the first two letters in the names and thus originate the error and confuse the record for a casual reader, but it is not speaking well for Galen's assiduity as a student of Plato that, quite aware of some confusion of names having arisen, he should not have untangled the snarl. It seems probable that Galen was led into error by this passage in Pliny, who wrote a hundred years or so earlier, but we can only guess at the cause of Galen's confusion and suspect him of carelessness in recording the sayings of his predecessors—a rather serious matter in one who is not only our most copious, but often our only, source of information as to ancient medicine. If one who wrote books on the theories of Hippocrates and Plato was too negligent to straighten out a thing of this kind ("no matter whether his name was Prodicus or Herodicus") we may easily believe our grasp on his predecessors whose works have perished is very slight indeed.

It was not the sickly Prodicus then, who, Xenophon says, wrote so eloquently of Hercules, it was the invalid Herodicus who trained athletes with his diet as well as chronic invalids and made people with acute fevers practise gymnastics to their detriment. Apropos of him we learn what both Plato and Hippocrates thought of athleticism in an age when it was carried to greater exaggeration than even in our own times. In this at least they are rightly quoted by Galen, who gives them his support after being an official physician of gladiators in Pergamum. Athletes, Plato says in the *Republic,* sleep away their lives and are liable to most dangerous illnesses if they depart, in ever so slight a degree, from their usual regimen. This I believe is borne out by our modern trainers and, though it has been disputed, breakdown of the vascular system in middle life is much more frequent among those who have long and persistently followed violent forms of athleticism in youth, but Plato was thinking of athletes as warriors in his Republic. The highly trained "flanneled fools," in Kipling's severe remarks on the same subject, did not stand up well in the ancient training of the soldier. Plato wanted warrior athletes to be "like wakeful dogs both to see and to hear with the utmost keenness; they will have to endure many changes of water and also of food, of summer heat and winter cold and with this they must not be liable to break down in health." Then Socrates, who himself had been such a hardy and brave campaigner in his younger days, expatiates for some time on simplicity in diet and temperance in all things. Simple food and moderate exercise make the best warriors for his model state. Licentiousness, Corinthian girls and drunkenness in the guardians of his republic can not be tolerated. "Of all men these should know where the ground is," the police of his state and the chauffeurs of ours as well.

One of the first of the *Aphorisms* of Hippocrates (I.3.) deals with athletes in the same spirit as the sentiment of Plato. It is not improbable that Plato's ideas were formed on it. Through some mutilation of the text, doubtless, the latter phrases of this aphorism are marred by an obscurity which neither Galen nor Littré have done much to dispel, but these apparently refer to the treatment of the disastrous results sometimes observed in the training of athletes. The opening clauses state emphatically the Hippocratic feeling on the matter much as Plato has here been quoted. Singular to say Adams in his translation uses a French word which the Frenchman Littré does not select and it changes the meaning of the opening clause considerably, whether we are to say *embonpoint* or *santé,* carried to the limit, is dangerous.

Since man never stands still and since he can not advance he deteriorates. The reference of course is to that training or overtraining which allows Nature no way for the variations which are an inevitable characteristic of living things. Adams thinks Herodicus gave Hippocrates instruction in the training of athletes, but if he did, this is very much in the way of an acute criticism on it from which the only escape is to make it a dispute about the meaning of the word.

Treatment of Infants.—Institutions for infant care developed very late in Paris. After institutions for children and orphans had existed for several centuries in many cities of France and the rest of Europe, it was not until the fourteenth century that there was established in Paris a special institution for receiving infants. We learn from Dr. Renoux (*Thèse de Paris,* 1924) that it still remains unique after almost two hundred years.

The Hôpital du Saint-Esprit was founded April 9, 1364, "by many good people moved with a great pity, charity and compassion." At one and the same time crèche, asylum, orphanage, even hospital, Saint-Esprit sheltered at least from one to two hundred children. There were also in Paris other institutions where children could be received at least temporarily with their mothers. Such was the Hôtel-Dieu, one of the "most sumptuous of Christian institutions." There were always in this hospital a great number of infants at the breast. From eighty to a hundred at least were received each year. In all the hospitals the mortality was frightful. King Francis I was so distressed by it that he ordered an investigation into the cause and the remedy. Five years later he established the Hôpital des Enfants Dieu, called Enfants Rouge because of the color of the uniforms worn by these orphans. This institution completed the Saint-Esprit; it was the first indication of the great flood of charitable works that was to sweep through the sixteenth century.—(Translated from *Æsculape,* February, 1925.)

Contributors to the Science of Medicine

Christian Albert Theodor Billroth

In modern times it is rarely indeed that we find a happy and successful combination, in the person of one individual, of the musical and scientific temperaments. In the Middle Ages such persons were not so scarce, but today is the day of the specialist. Theodor Billroth, born in 1829, was an exception to this rule. He was a learned and accomplished musician, and at the same time one of the most successful surgeons of his time.

Billroth's birthplace was Bergen, on the beautiful Island of Rügen. His family life and early surroundings were of the happiest and most highly cultured. At an early age he gave evidence of a love and real talent for music, which he always insisted were hereditary. His grandmother had been a well known soprano at the Berlin Opera House and his wife's grandfather was the famous tenor Eunicke who created the rôle of Florestan in Berlin. Had he had his way as a boy, he would have dedicated his life to music, but his mother prevented him from doing so, a procedure for which he seems later to have been grateful.

Theodor, after completing the courses at the gymnasium, went to the universities of Greifswald, Göttingen, and Berlin, in the last of which he received in 1852 his degree in medicine. The title of his thesis was *Concerning the Nature and Causes of a Pulmonary Affection Arising from Section of the Vagus.* It was considered at that time to be a contribution of unusual merit and of great promise. Among the famous men under whom Billroth studied were Rudolf Wagner, Müller, Lotze, Schönheim, and von Graefe. He did notable work not only in his specialty, surgery, but also in normal and pathological histology, physiology, and general pathology. After postgraduate courses at the universities of Vienna and Paris, he was appointed assistant to Langenbeck at the Royal Clinic at Berlin University, where he became a brilliant operator. Among other prominent positions which he held were those of Privat-Docent at Berlin University and chief professor and director of clinical surgery at Zurich University.

His first great published work, *General Surgical Pathology and Therapeutics,* achieved, as soon as it was issued, the most notable success, and was subsequently translated into Italian, Spanish, Hungarian, Polish, Russian, Servian, Croatian and Japanese.

Like all exceptionally great men, Billroth had to combat much antagonism and opposition on the part of his own profession. When, at the height of his fame and in the full flower of his activity, he accepted the chair of surgery at Vienna, and attempted to introduce some of his own progressive methods and ideas with a view to reorganizing the clinic in accordance with the most advanced standards of medical science, he aroused a veritable storm of opposition. However, through the sincerity and charm of his personality, and the employment of tact and patience, he finally succeeded in overcoming the greater part of the antagonism and in estimating many of his own ideas and practices. Here, as everywhere, he came to be greatly loved and admired by all who came in contact with him. His handsome face and figure, charm and brilliancy of manner, and unquestionable genuineness and sincerity, coupled with his fluency of speech and freedom from all doctrinal tenets attracted and gained for him the friendship of many persons in all walks of life. Ideas quite new to his pupils were developed and pathological phenomena as they appeared at the sick bed were explained in the light of the latest discoveries in physiology, pathological anatomy and experimental pathology. "The soul of science breathed life into his teachings; the love of truth, with which Billroth was completely saturated, made them real," writes Dr. Hammeter in his biographical sketch of the great German physician.[1]

Probably the greatest contribution of Billroth to medical science was in the domain of practical surgery. During the Franco-Prussian War he was a military surgeon and his letters written from the military hospitals where he served are remarkable and invaluable documents. Upon his return from the field hospitals, he resumed his investigations of the vegetative forms of septic cocci, on which he wrote one of his most famous monographs. At this time he frequently would work from sixteen to eighteen hours a day. After the completion of this investigation and the monograph on its results, Billroth with characteristic energy and versatility began a study of the arrangement and character of courses in medicine in the universities of all countries. The results of this investigation are recorded in his book, *How to Teach and Study the Medical Sciences.* This is still a veritable treasure house of information and ideas. Among his other works were monographs and treatises on wounds, scrofula, tuberculosis, diseases of the mammary gland, historical and critical studies of transportation of the sick and wounded, home and hospital nursing, and other medical topics. Even up to his last illness, Billroth always retained his keen interest in and knowledge of medical science, so that his information was never out of date. One of his unusual contributions was a fine collection of illustrations of rare diseases made under his direction by the celebrated artists of that time. Billroth performed the first successful extirpation of the larynx, and the first resection of the stomach.

The great physician had, too, a remarkable degree the ability to adapt himself to many varying types of personality, even those that differed widely from himself. He had also the gift of inspiring his pupils and of handing down his work through them to posterity. Because of his great love of music, he trained himself to be an able performer on several instruments, and was recognized as a musical critic of marked ability. He was also an artist in his tastes, as was shown by his beautiful Villa Billroth. Here

[1]Johns Hopkins Hospital Bulletin, Vol. XI., 1900, p. 297.

he and his wife, Christel Michaelis, would receive their many friends from prominent Viennese families; yet these were made no more welcome than the poor students from the universities who were taking Billroth's courses. Perhaps because it was the principal musical centre of the day, Vienna became the chosen and beloved city of the great scientist. He endowed many of her charitable institutions, among them the Rudolfiner Association with its hospital at Oberdöbling, and the building of the Royal and Imperial Society of Physicians in Vienna. When he died, the government assigned to him a grave of honor, and a throng of thousands of mourners followed the funeral cortege through the streets.

In musical circles Billroth was known not only for his masterly performances on the piano, violin, and viola, but also for his many musical criticisms published in the papers and journals, and for his book, *Who Is Musical?* In this he attempts to clear up the entire subject of physical and physiological acoustics, and to blend and relate to each other the esthetic aspects of music and its physical and physiological aspects. He conceived of music as standing in a much closer relation to pure sensation than any of the other arts, which deal rather with what the senses apprehend.

Dr. Hammeter sums up as follows Billroth's contribution to the world: "He was a man who represents one of the most scholarly, versatile and inspiring characters in the history of German medicine; an investigator who accomplished and perfected achievements of enduring excellence in two arts widely divergent—music and surgery; or, to state it in broader terms, in biology and medicine as well as in the psychology of music."

The Contributions Which Women Have Made to Medical Literature.—Metta M. Loomis, librarian of the College of Medicine of the University of Illinois, writes (*Medical Woman's Journal,* December, 1924) that the first woman known to have written on medical subjects is honored by the commendation of no less an authority than Galen, who advises those who would learn of midwifery to consult the writings of one Cleopatra. A knowledge of the works of Aspasia, who wrote on the diseases of women, would also have been lost to the world except for references and quotations which were made in certain manuscripts dating back to the sixth century B. C. St. Hildegarde of Bingen wrote a book, *Physia,* which ranked with the best medical writings of her age, the twelfth century. It showed that its author was thoroughly familiar with the practice of medicine of her day. At the University of Salerno several professorships were held by women who also wrote on medical subjects. The most famous of these seems to have been Trotti, called Dame Trot, who wrote a book on gynecology which circulated beyond her own country. A textbook on surgery and another on gynecology were written by two other women professors and were used as textbooks for many years by medical students. Mondino received valuable help from his assistant, Alexandria Galiani, while he was writing his great work on anatomy.

After this early period of achievement, we find no women contributing to medical literature until the middle of the eighteenth and the beginning of the nineteenth century, when German and French midwives wrote books that ranked as authorities until the science of bacteriology revolutionized the practice of gynecology and obstetrics. Madame La Chapelle's *Practice of Obstetrics* is a work in three volumes which appeared from 1821-25, and was translated into German. The numerous and valuable tables of statistics compiled from her fifty thousand cases show remarkable pains in the keeping of case records and served to establish the norm for obstetric procedure at that time. Madame La Chapelle states that she consulted all authorities beginning with Hippocrates.

Madame Bovin, for a short time associated with Madame La Chapelle, was a more prolific writer and her works are equally worthy of note. Her best known book on *The Art of Obstetrics* was published in 1812 and was commended by the General Council of the administration of the Paris city hospitals. Others of her books are *One of the Most Frequent and Least Known Causes of Abortion;* and her work on diseases of the uterus and its appendages was used as a text book for many years. The University of Marburg conferred upon her the honorary title of Doctor of Medicine. Louise Bourgeoise was another of the noted French midwives, but her writings are less valuable from a scientific than from a literary and historical standpoint.

In Germany were Justine Siegmundin, court midwife, and Elizabeth Hornburg, midwife to Marie de Medici. The former's book is called *The Midwives of the Royal Family of Prussia and of the Kurfurst von Brandenburg.*

The modern activities of women in connection with the practice of medicine began in the United States about the middle of the last century when the Blackwell sisters entered upon the study of medicine. It was not until two decades later that women began to study medicine in England and Russia, and fifteen years later that the movement reached France, Germany and Scandinavia. The first American woman to contribute papers which really added to the general knowledge of medical science was probably Dr. Mary Putnam Jacobi, whose works on abdominal hysterectomy and uterine fibroids were the results of original research. A book published in 1891 called *Woman's Work in America,* includes a list by Dr. Jacobi of 154 articles written by forty-one women in medicine. A history of the Woman's Medical College of Philadelphia lists 573 articles by graduates of the college prior to 1897. The first volume of the *Index Medicus* published in 1879 lists twenty-one articles by ten different women; eight of these were Americans and two French. In the 1912 *Index Medicus* are 616 entries of books and articles written by women, 459 in number. Of these articles, 261 were published in America, 108 in France, 61 in England, 53 in Germany, 6 in Russia, 4 in Italy, 6 in Belgium, 2 in Poland, 10 in Switzerland, 2 in Austria Hungary, 1 in Australia, and 1 in Manila. The greatest number contributed by any one woman was by Kol-Yakimova, a Russian, who wrote twelve different articles published in German, French and Russian.

Of modern names, France has the most illustrious, Madame Curie; Italy boasts Madame Montessori's

medical works. The writings of Florence Nightingale and Ellen Richards have probably contributed as much as any toward quickening the public conscience to a realization of its sanitary obligations.

The writer concludes her paper with a summary of the work of the most important of the presentday women writers on medical subjects. A bibliography completes the article.

The French Cantinière, Humble Forerunner of the Red Cross Nurse.—Norah Hill writes (*World's Health,* December, 1924) that many students of medical history will be surprised to learn that there were women caring for the wounded on the battlefield of Solferino. An old book, *Cantinières et vivandières françaises,* traces the whole history of the French cantinière from her earliest appearance to the end of the Franco-Prussian war. Two cantinières, this book tells, were decorated for bravery at the battle of Solferino. One, "young and beautiful," took a small cask of brandy, one of water, and a small roll of linen and went among the wounded as a Sister of Charity. She herself, wounded in the arm, refused to leave the field of battle and managed to drag a soldier, wounded in the thigh, to an ambulance by having him cling round her neck. Meeting a surgeon just afterward, she had her mutilated fingers amputated then and there. Later, her ring, torn by shot, was presented to the Emperor, who handed her the military medal in return.

However, the history of the cantinière began much farther back, for Tacitus mentions her as having been seen in the German armies, accompanying the soldiers, carrying food for them, dressing their wounds and exhorting them to bravery. The Gauls also often took their women and children with them when they made war; in fact, as is well known, this custom persisted through the Middle Ages, to such a degree that one French writer attributes the outbreak of plague in 1639, which almost destroyed the French army, to the hordes of women and children always around the camps. Many of these were women of illrepute, he states, but these are not to be confounded with the cantinières, who were usually wives of the soldiers.

The custom originated in the venerable custom of taking in washing. From washing the regimental linen, they passed to keeping the regimental canteen. "But the canteen of those days was not simply a vulgar eating house; it was a meeting place where the young recruit was welcomed and initiated, and where the veteran soldier refought his campaigns; it was a sort of infirmary where first aid, in the shape of cordials, was administered to the wounded. The cantinières, however, were not content to give first aid only in their canteens; during battles they went out under fire and picked up the wounded and afterwards helped the surgeons to dress their wounds. More than once they were themselves wounded; and more than once did an enemy shell destroy their provisions, their sole wealth, but that did not hinder them from giving drinks to the dying without hope of reward, or from tearing up their own linen in order to dress the soldiers' wounds."

In the stories of Napoleon's campaigns, frequent mention is made of the cantinières. During the passage of the Piava, a cantinière saw a soldier being carried away by the current, and threw herself into the river and saved him. For this she received from Napoleon a gold chain and crown, thus earning the honor of being the first cantinière to be decorated. (I regret to say, however, that the gift was engraved, not with her name, but with the name of the soldier whom she saved!)

The costume of the cantinière was a tall hat with plumes and a chin band, and a long cloak; she rode a horse among her brandy barrels and provisions. If her husband was promoted, sometimes she became "Madame la Générale," or "Madame la Baronne." The names of some of the cantinières that have been handed down in history are Cathérine Rohmer, Joséphine Trinquant, and Thérèse Jourdain.

In 1830 an official uniform was prescribed for them, but not officially provided, however. This consisted of regimental trousers, a short, full skirt of red braided with blue, a short coat with brass buttons, a little white apron, and a red képi or hat with a bunch of tricolor ribbons in it. The little brandy barrel, an indispensable part of the costume, was painted red, white and blue.

The Manor of Laennec.—Dr. De Backer and Dr. Larbaud write (*Æsculape,* February, 1925) that while they were spending a month in a vacation resort of Brittany near Douarnenez, close by Laennec's former estate, they were so struck with its beauty, and with the reverence in which the name of the great master is still held by the natives, that they felt they must record some of their sentiments. Their article is attractively illustrated with reproductions from pastel drawings. The whole scene as depicted by the two writers is marked by the simplicity and modesty which characterized Laennec himself and his life. The old manor house, dating from the middle of the seventeenth century, has kept all its beauty in the perfect simplicity of its lines. It is located in a large park containing beautiful old trees of many varieties, especially pines, and is screened by a high hedge. The writers, after giving a detailed description of the house, add: All this has the same beautiful simplicity as the Master himself. It was to this pretty nook that he came to recover from his work and from the fatigues of Paris. There he lived happily, a lover of the soil, a modest and frugal life. Agriculture interested him greatly, hunting passionately, and it was not unusual to see him going to church with his gun on his shoulder. On his walks through the woods and fields, he would meet the peasants, and give them advice about their health and the cultivation of their fields. The whole countryside knew him and adored him for his modesty and simplicity. The old people still are happy when their are telling naive stories about him, handed down from their fathers. And all is of his kindness and devotion. He was so adored by the peasants that they quarreled over the privilege of drawing his little carriage when he went to mass or chapel.

After his death at the age of only forty-six, he was buried in the Cemetery of Ploaré, overlooking the village of Douarnenez, with the sail studded bay on one side, and on the other a smiling valley with bouquets of trees and clusters of little houses. The whole cemetery is a garden, in which his simple grave stone marks a well tended grave.

THE MENACE OF RHEUMATIC DISEASES

To those diseases massed together under the name of rheumatic diseases may be ascribed a large proportion of the mortality and invalidism of civilized countries. Rheumatism in its various forms is essentially an industrial disease. It kills, cripples, and in other ways renders unfit for strenuous active labor a large part of the working population of all countries. In Great Britain, for instance, it has been stated on the authority of the Ministry of Health that nearly one sixth of the industrial invalidity of the country is due to diseases classed as rheumatic. Each year these diseases are costing the benefit societies nearly ten million dollars for sick benefit, and the nation over three million weeks of work. Half this loss, both of money and time, is due to chronic joint diseases. Similar statistics covering the entire country are not available for America, but from known figures it seems likely that this continent is not far behind the continent of Europe so far as the incidence of rheumatic diseases are concerned and that industrialism is as much hampered here as elsewhere by the havoc wrought by these maladies.

Moreover, and this is the most arresting feature of the situation, acute rheumatism is largely responsible for heart disease in young children from which they never really wholly recover and which is the cause of immense mortality. Heart disease in the young is known to be very prevalent in this country and therefore it may be taken as proved that acute rheumatism attacks children with deplorable frequency. Chronic heart disease throws a large burden of invalidism on a country which taken in conjunction with the cost in money and time lost due to rheumatic diseases mentioned above reaches a stupendous sum. If rheumatism can be prevented, even to some extent, the saving in death, suffering and money will be such as to be sufficient excuse for putting into force any measures which seem likely to further this object. Undoubtedly measures of this nature will be largely of a preventive character.

In the first place, what causes acute rheumatism? While this is not known definitely, the findings of the majority of observers are in favor of the view that tonsillar infection is an etiological factor which must not be overlooked. Clinical evidence shows that a considerable proportion of patients with acute rheumatism suffer from enlarged or septic tonsils. Dental sepsis appears to be associated so frequently with fibrositis in its various forms and with diseases distinguished mainly by chronic joint changes as to lend color to the view that if this condition does not produce these forms of rheumatism at least it predisposes to them. This question requires and is worthy of further careful investigation before definite statements can be made. But negative clinical evidence goes to show that a large percentage of rheumatic patients exhibit dental sepsis and oral sepsis in one form or other and that in those patients with chronic joint diseases the percentage is higher.

With respect to acute rheumatism it would no doubt simplify matters if we had more precise knowledge as to the causal organism. Lacking accurate knowledge there is one feature of acute rheumatism which is known and this knowledge should be acted upon. An attack of acute rheumatism confers no immunity but favors recurrence rather than immunity. Therefore, the primary object is to prevent a first attack and then to prevent subsequent attacks. Permanent damage is done to the heart more frequently by second and subsequent attacks than by a first attack. Attention may be directed to the point that although figures show that acute rheumatism has declined in incidence in this country and Great Britain, it appears likely that this decline is more evident in adults than in the young. The prevention of dental sepsis, and of enlarged tonsils and adenoids, falls perhaps chiefly within the sphere of medical school service.

The avoidance of nonarticular rheumatism is an industrial question of first importance, because muscular rheumatism, lumbago, sciatica and brachial neuritis are very frequent among workers, both men and women. The haziness which exists with regard to the causative organism of chronic joint diseases is more murky than that which obscures the causal organism of acute rheumatism, and consequently we are more at sea with regard to measures of prevention. To an unfortunate extent, we are groping more or less in the dark. We stand fairly in the light as to a few points. It is known that enlarged or septic tonsils predispose to rheumatism and the same may be said as to dental sepsis. Oral hygiene is therefore strongly indicated. Gastrointestinal troubles in themselves would appear to predispose to rheumatism and of course they react on the mouth and teeth. Consequently gastrointestinal disorders should be nipped in the bud as far as is possible and when established should be seriously dealt with. Diet and modes of eating should be supervised carefully and domestic hygiene, including the avoidance of dampness and chill, should be a part of the policy of prevention. In addition, however, the use of therapeutic measures should be initiated in many

cases and the gastrointestinal and urinary tracts should be subjected to disinfecting treatment. And it must be borne in mind that it is essential to cleanse the urinary tract, as the gastrointestinal tract becomes infected when the urinary tract is involved. In preventing and treating rheumatism, it is simply common sense to purify and keep clean to the utmost extent the digestive, intestinal, and urinary systems.

The menace of rheumatism mainly as an industrial disease is national, nay international, and every civilized country is intimately concerned. It is hoped that the symposium on rheumatism which we present in this issue may throw light on some features of a disease which has baffled investigators from time immemorial. It may be recalled that from the earliest periods, as shown by skeletons, man has been afflicted with osteoarthritis. In any event, this collection of articles should occasion renewed interest in a disease which is destructive and worldwide and, perhaps, may provoke discussion.

ENDOCRINES AND RHEUMATIC DISEASES

Life has its "little ironies" and medicine, too, is not devoid of them. Thus, is it not precisely those diseases with which we are most familiar that we know least about? Gout has been known to us for centuries, but its cause is still unknown. Rheumatic fever as far back as 1640 was recognized as a clinical entity, but its origin is still a mystery. Of the two, it is the latter that clamors most urgently for elucidation.

It is asserted that in the British Isles there are no fewer than fifty thousand children of school age who are the victims of organic heart disease. Again, the statistical bulletin of the Metropolitan Life Assurance Company, New York, states that about one in every five of the population living at the age of ten will ultimately succumb to organic heart disease. Clearly then, this problem of the rheumatic child is one of worldwide importance, and the call for the removal of such a menace is as insistent as ever it was for tuberculosis. Like the latter, it must be dealt with as a matter of public health. Hence the incumbency of a more judicial attitude on our part towards this intricate problem, one as far removed as possible from the influence of etiological suggestions with their aftermath, a restricted field of vision.

Convinced as many are of the infective origin of rheumatic fever, there is unquestionably another side, which calls for deliberate consideration. We can ill afford to leave any avenue unexplored. It is not a question simply of infection but of something vastly wider and more profound in a biochemical sense. For, as many maintain, if hypothyroidism is infinitely more common than is generally conceived, then we have to face the fact that a vast number of children start life crippled, in a metabolic sense, by their lack of thyroid hormones. Moreover, if we dwell for a moment on the farreaching cellular consequences of such thyroid famine, we see that the superficial minor signs of thyroid inadequacy are but the outward reflection of occult metabolic obliquities involving cellular metabolism as a whole. This being so, it may well be, as Llewellyn suggests, that the first stage of the rheumatic heart in a child may be purely metabolic, a failure in nutrition of the cardiac substance due to deficient or perverted thyroid hormones, and surely nothing could so favor a secondary implantation of wandering microbes. It is in truth the rheumatism of childhood that calls for intensive research, if we would eradicate this scourge.

Llewellyn's suggestion that rheumatism in childhood arises from a subthyroidic substrate, should, if confirmed, appeal to many, in that it opens up a possible avenue whereby this menace of childhood may be prevented, or its effects controlled or minimized. The nervous instability of rheumatic children is notorious, and their proneness to tetany and symptoms of vasomotor ataxia are distinctly suggestive of some inherited endocrine instability. That rheumatic fever occurring in the children of the actually goitrous, or those living in endemic areas, may prove obdurate to salicylates and yet respond if thyroid be superadded, may be not only a therapeutic boon but, as Llewellyn suggests, an etiological hint of profound significance. It raises the possibility not only that subthyroidism portends a greater liability to rheumatism, but also that its timely correction may haply stave off rheumatic fever or cardiac rheumatism. It clearly indicates that school officers must be quick to detect the minor signs of hypothyroidism in children. Especially in children coming of rheumatic stock should we be alive to the possibility of inherited thyroid deficiency or instability. Again, if the children live in goitrous districts iodine prophylaxis and the provision of a bacteriologically pure water supply are clearly of paramount importance, especially if it should transpire that the incidence of rheumatic diseases is markedly higher in goitrous as opposed to nongoitrous localities. For it seems certain from the observations of Berry and McCarrison that goitre is prone to develop in marshy, badly drained neighborhoods, with which rheumatism also has been from time immemorial associated.

Nor can we overlook the fact that not only rheumatism, but rheumatoid and osteoarthritic affections are apparently more common in goitrous districts. Thus, McCarrison states that in goitrous regions of

the Himalayas the prevalence of rheumatoid arthritis among the victims of goitre is such as to suggest a similarity of origin. That the osteoarthritis of women at or after the menopause is frequently associated with goitre or subthyroidism is generally admitted, and in short the evidence that rheumatoid arthritis and osteoarthritis are intimately associated with thyroid disorders is undeniable. The latter may take the form of Graves's disease, or states of hyperthyroidism or more often hypothyroidism, or actual myxedema frequently correlated with goitre. Moreover, the dramatic manner in which rheumatoid arthritis and osteoarthritis respond to thyroid therapy when given in suitable cases strongly suggests that thyroid inadequacy or instability favors their development. The fact that rheumatoid arthritis and scleroderma have followed thyroidectomy or exposure of the thyroid gland to x rays is highly suggestion of a causal nexus. Moreover, we have Deaver's recent statement that after partial thyroidectomy for goitre, especially the toxic variety, resistance is lowered to rheumatism and acute endocarditis.

Reverting now to rheumatic fever, French physicians have long insisted that subacute thyroiditis is commonly present at the onset or during the course of the disorder. That this fact should not have attracted more attention in other countries is somewhat astonishing. It may well be that this is due to the fact that not only is the thyroid swelling usually slight and fleeting in duration, but occasions no spontaneous pain. Despite absence of pain, however, the thyroid lobes are exquisitely tender if compressed digitally. It may well be then that routine palpation of the thyroid in rheumatic fever may reveal that such tenderness of the thyroid is present as Vincent claimed in sixty-eight per cent. of the cases. The thyroid swelling or tenderness usually responds to salicylates, and more swiftly than the joint swellings. On the other hand, it may persist, and the symptoms of hyperthyroidism or even Graves's disease be superadded.

In conclusion, we would plead for a more open mind in regard to the etiology of rheumatic and rheumatoid disorders. The following points seem worthy of further research. To begin with: Are rheumatic disorders generally more prevalent in goitrous than in nongoitrous areas? If so, has the installation of iodine prophylaxis been followed by diminution in their incidence? Do children of rheumatic stock commonly show signs of hypothyroidism? If so, timely thyroid therapy might diminish their liability to cardiac rheumatism. Research along such lines could not fail to be helpful, for unquestionably the etiological relationship of goitre to diseases other than Graves's syndrome, myxedema and cretinism urgent calls for investigation and research in the sphere of arthritic disorders.

HOLMES ON HYGIENE

The names of Osler and of Allbutt remind us, in their passing, of the few physicians who stand out as men of great culture or, rather, as men who have exhibited in their writings signs of distinction in general learning. None, however, have shown greater brilliance than our own Oliver Wendell Holmes, who sang in many keys and with lasting impression.

In this day of the writing of many popular or intended to be popular books on health, it will be interesting to many that Holmes also wrote, and in the most entertaining manner, on this subject. His definition of life contained in this essay is certainly as sensible as any: "Life is the state of an organized being in which it maintains, or is capable of maintaining, its structural integrity by the constant interchange of elements with the surrounding media." He remarks: "One would say that the regulation of the conditions of the body should be as simple as the ordering of the conditions which enable a skilful agriculturist to raise healthy vegetables and fruits. There are only two difficulties, we cannot choose our constitution and we cannot always command many of the circumstances which have most influence on health."

Speaking of vegetarians, he says: "It is easy to understand the repugnance with which fastidious persons regard the act of devouring the flesh of animals. The fanatics on the subject are sometimes terribly abusive, as I have had occasion to know. Yet I have had refreshing seasons of converse with vegetable feeders, who are commonly of a speculative turn of mind and amuse unbelievers with their curious fancies. Theories commonly go in sets like chamber furniture, and you will find a mind furnished throughout, physiologically, philosophically, morally, theologically, in the same shade of color, and with the same general pattern prevailing through all its articles of belief."

On the subject of drinks he writes: "Alcohol itself can hardly be said to be used as a drink at all, though the jars containing preparations, anatomical or other, in museums, are said to have sometimes lost their contents too rapidly for evaporation to account for. There is no need of dwelling on the ruinous effects of overindulgence in strong drink. Neither is there any use in telling lies, still less in legislating them. The habitual use of alcoholic fluids in the form of wine does not prevent men and women from living long, active, useful, healthy, and virtuous lives. Four of those whom I most honored in the

last generation drank wine daily all the years I knew them. Their age reached an average of between eighty-seven and eighty-eight years, and yet not one of them was of robust habit, or promised to attain any remarkable longevity.

"We cannot disguise the fact that men 'drink' because they like it, much more than for any good they suppose it does them, beyond such pleasure as it may afford; and this is precisely the point that all arguments fail to reach. Pleasure is the bird in the hand which foolish persons will always choose before the two birds in the bush which are to be the rewards of virtue. Intoxication offers to the weak or illmanaged brain a strange, pleasing confusion, a kind of Brahma's heaven, 'where naught is everything and everything is naught,' and where all perplexities at last resolve themselves into the generous formula, 'it's of no consequence.'"

All this was written a half century ago and, while there has been much legislation, the why and hygiene of alcoholic indulgence remain the same.

On the matter of clothing Holmes is especially happy. "The subject of clothing is understood well enough, and the rules of commonsense are well enough observed by men. But woman is under the guidance of a higher law than any relating to her individual safety. . . . It is in virtue of this supreme indifference to consequences,—this sublime contempt of disease and death as compared with the loss of the smallest personal advantage,—that woman has attained the power of resistance to exposure that so astonishes the male sex. Think of her thin shoes and stockings, her bare or scarcely protected neck and arms, her little rose leaf bonnet, by the side of the woolen socks, the layers of flannel and broadcloth, and the warm hats and caps of her effeminate companion! Our cautions are of no avail except to the fragile sex,—our brothers in susceptibility and danger."

PROGRESS IN THE TREATMENT OF ANKYLOSIS

Dr. J. B. Murphy of Chicago and Dr. Payr of Germany were among the first to operate for the improvement of a joint rendered immovable by bony ankylosis. Murphy, who was a remarkable surgeon, had a considerable amount of success with such operations and as a matter of fact his methods are used by many orthopedic surgeons of the present day. Progress, however, has been made in this direction, evidence of which is given in a paper read by Dr. W. Russell Macausland of Boston before a meeting of the Section of Surgery of the Massachusetts Medical Society, held at Swampscott, June 7, 1924, and published in the *Boston Medical and Surgical Journal,* October 6, 1924. The object of arthroplasty is that it is a surgical technic calculated to improve the function of an ankylosed joint, and therefore only those joints which can be improved by such a method are considered suitable for arthroplasty. These joints are the elbow, the hip, the knee, the temporomaxillary and the wrist and fingers. Other factors, as Macausland pointed out, must be taken into consideration before arthoplastic measures for the mobilization of any joint are advised.

The disability of the patient is of the first importance, for a stiff member that is a great disability to one patient may be of only slight discomfort to another. No attempt should be made to mobilize a joint until epiphyseal growth has ceased. If an operation is performed earlier it is impossible to remove sufficient bone to secure good motion with grave risk of injury to the epiphyseal line.

Macausland summarized the fundamental indications for arthroplasty as follows: 1. Two stiff hips indicate operation on one joint or possibly both; 2. Two stiff elbows present the same indication; 3. Two stiff knees are a definite indication for arthroplasty, on one side at least; 4. A combination of ankylosed hips and knees in the same individual, a condition not infrequently seen in multiple arthritis, is a very definite indication for attempting to mobilize one or more joints. Stiff shoulders, stiff fingers, stiff wrists and stiff maxillary joints may be dealt with also by arthroplasty. Aftertreatment is of the first importance as the ultimate success depends very largely on after treatment. Consequently, the patient should be under observation for a long period of time.

The bony changes of the joint should be followed by frequent radiograms and appropriate treatment when necessary should be performed in accordance with such changes. The knee joint is the most difficult of the joints to treat by arthroplasty and only the type due to intraarticular pathology is amenable to treatment. Owing to the fact that the new joint must be satisfactory not only as to function, but it must be absolutely adapted to weight-bearing that is free from pain and sensitiveness, the knee joints present very great, according to some orthopedists, almost insuperable difficulties, to the successful performance of arthroplastic methods. Macausland holds that two stiff knees or a stiff knee and a stiff hip, provide a definite indication for operation on one knee at least.

In the discussion that followed the reading of the paper Dr. N. Nathaniel Allison, of Boston, adversely criticized arthroplasty for knee ankylosis, stating that only an occasional success was obtained. He also gave it as his opinion that ankylosis is frequently

reestablished and explained why, and he did not think that arthroplasty should be represented as an easy or uniformly successful surgical procedure.

Dr. Macausland in replying to the criticisms on knee joint arthroplasty argued that when there were two stiff knees and hips and other combinations of ankylosis it was necessary to try something, and he and his colleagues could show a great many patients who had been treated for these and similar conditions, with decided improvement in function. He contended that one of the greatest objections to knee joint arthroplasties was instability and that instability had been due to improper modelling and after care, and this in most cases should have been avoided. There is no doubt that while arthroplasty is not a perfect operation and there is room for much improvement, considerable progress has been made. Dr. Macausland in this country, Putti in Italy and Hey Groves and Sir Robert Jones in Great Britain have been largely responsible for this advance.

AGAINST THE PRICKS

In medicine, curative and preventive, we are constantly kicking against the pricks, not only to no avail for the time being, but with the production of more harm than good.

It does not sound well for humanity to have an average number of days of absence from business on account of illness or average rates of sickness, whether the sick are engaged in business or not, but we are a long way from getting rid of illness, and even higher sickness rates might conduce to lowered death rates. This may sound paradoxical, but the fact is that it is the people who are not able to be about but who *are* about, who make best food for germs and premature candidates for the undertaker.

Especially does this apply to the matter of colds, whether these be "common," "influenzal," "bronchitic," or "pneumonic" or other. For the most of us there is not, at present, with all due hygiene, any long immunity to colds, and sooner or later they are bound to get us whether we do or don't "watch out." We might as well acknowledge this and take to our beds at their onset and stay there until we can safely leave them. A safe outcome will be more certain, and the immunity conferred for the nonce will be none the less.

It is a wise virtue to be ashamed of being sick and of lying up, but it is no virtue, nor is it at all valorous, not to acknowledge our lack of resistance to something to which, willy nilly, we have fallen a victim.

The outcome of colds (or what seem to be colds) would be made more certain, and their spread would be lessened if employers would make it plain that sick leave, equivalent to the present enforced absence for sickness (or even more) were assured to every employee.

The patient who believes he has "only a cold" and who seemingly has only a cold (though it is as likely, perhaps, to be influenza) is one of the most troublesome of patients. He invariably expects to receive a magic drug which will cure him instanter and allow him to return to work on the morrow. Even the recommendation of a hot bath, hot lemonade and an "early to bed" with plenty of blankets is secretly resented as trite and trifling, coming from a man who has studied medicine for a tenth of a lifetime. To insist that the man (or woman) with the cold stay in bed a day or two, or even remain in a room at one temperature for that length of time, may not conduce to attract the patient on another occasion, but it is the best practice and the only safe practice.

If the heads of big business, those who make their income out of human health, would be sufficiently considerate of human health to threaten it with dismissal if it does not keep itself in health, and should insist on paying it to take care of itself, such treatment of colds would be more appreciated, the working capacity would be heightened, and the deaths from respiratory diseases which now head the horrible list would be decidedly diminished. This would be more conducive to Karma in the great amassers of money than the financing of libraries or the building of hospitals, and the accumulation of money for the latter purposes would not be lessened.

Obituary.

SIR RICKMAN JOHN GODLEE, BART., K.C.V.O., M.B., M.S. (Lond.), F.R.C.S. (Eng.)

London

Sir Rickman John Godlee died suddenly on April 20th at his home a few miles from London. Godlee was a Quaker and a nephew of Lister. He graduated in arts at the University of London at the age of eighteen and entered University College Hospital as a medical student. He had a distinguished medical career and was a remarkably good anatomist and an extremely skillful draughtsman. So skillful a draughtsman was he that he was employed to make the original drawings for the plates of *Quain's Anatomy*. These drawings he presented to the Royal College of Surgeons in 1920. They are preserved in the library and comparison shows how infinitely superior they are to the plates made from them.

He became a member of the Royal College of Surgeons in 1872 and in 1876 took the fellowship. He also took the M.B. and M.S. of London University, being awarded the gold medal for surgery. He then went to Edinburgh, where Lister was a professor, to study his uncle's methods, and on returning

to London became surgical registrar at University College Hospital. There being no vacancy on the staff of University College Hospital at the time, he was elected assistant surgeon to Charing Cross Hospital and the Queen's Hospital for Children. In the following year he was elected assistant surgeon at University College Hospital and demonstrator of anatomy in the medical school. He was the constant assistant of Lister and was an expert surgeon. He performed one of the first major brain operations.

Godlee in 1884 was elected surgeon to the Brompton Hospital for Tuberculosis. He worked there for more than twenty years and wrote in collaboration with Sir James Kingston Fowler *Diseases of the Lung,* which was for long regarded as a standard book on the subject. It showed how great an extension of surgery had been provided by the development of antisepsis and bacteriology. In this book Godlee was responsible for that part dealing with the surgery of the lung and pleuræ.

In 1911 he was elected to the presidency of the Royal College of Surgeons. He gave the Bradshaw Lecture in 1907 and was Hunterian orator in 1913. In 1912 he was made a baronet. He was surgeon to the household of Queen Victoria, and later Surgeon-in-Ordinary to King Edward XII and King George V. During his term of office as president he went to America to deliver an address on the occasion of the foundation of the American College of Surgeons of which he was made an original member.

During the war he was chairman of the Belgian Doctors' and Pharmacists' Relief Fund, of which the editor of the *Lancet* was secretary. After the war Godlee practically retired to the country, where he occupied his time in country pursuits and in writing the biography of Lister.

Godlee, in addition to his professional skill, was an accomplished linguist, excellent water color painter, a good botanist and orinthologist, a farmer, a gardener, and no mean oarsman. He was an unassuming man whose Quaker training was exhibited throughout his life.

E. E. KLEIN, M.D., F.R.S.

London

Dr. E. E. Klein, who died February 9th, last, in London, at the age of eighty-seven, was one of the founders of bacteriology, a pioneer in modern normal histology Klein was born at Ersec, near Vienna, on October 31, 1844. In 1869 the New Sydenham Society in London determined to publish a translation of the *Manual of Human and Comparative Histology,* edited by Professor Stricker of Vienna. Professor Stricker had need of someone to arrange terms for the translation of the book and chose for the purpose Dr. Edward Emanuel Klein, the son of a Hungarian merchant. Klein, when he arrived in London, could speak no English, but brought introductions to the leading men of science of the day, Huxley, Burdon Sanderson, John Simon, and Henry Power. His manners, his evident knowledge, and good looks made a favorable impression upon the members of this circle, but when his work with respect to Stricker's affairs was completed, he returned to Vienna at the end of 1869 to continue teaching histology and embryology. In April, 1871, he was invited to return to England to undertake some histological and pathological researches in disease. He came and joined the staff of the Brown Institute, was given the title of assistant professor and placed under the direction of Burdon Sanderson, the superintendent of the institution. Here he worked strenuously, and issued a series of valuable reports on various acute and chronic infective processes. His findings and theories based thereon were so original that he was elected a Fellow of the Royal Society in 1875, while these findings and methods formed the foundations upon which the science of bacteriology was built. In 1873 he was appointed lecturer on histology at St. Bartholomew's Hospital. At about the same period he wrote the section on histology in the *Handbook for the Physiological Laboratory.* In 1879, together with Mr. Noble Smith, a well known orthopedist who was also a remarkable draftsman, he published a beautifully illustrated atlas of histology, and in 1889 a small but comprehensive *Elements of Histology,* which had a great vogue.

However, the real work of his life was investigating the origin of disease. He published the results in 1884, *Microorganisms and Disease;* an Introduction to the Study of Specific Microorganism. This book was the textbook on the subject up to 1896, when the science of bacteriology had arrived, and more advanced books were required. Klein gave up teaching histology in 1902, and was appointed lecturer on advanced bacteriology. At the same time he went on with his researches for the government, and among other work made a special investigation as to the causation of oriental plague.

News Items.

Hospital in Rheims.—The American Memorial Hospital for Children, at Rheims, France, has been formally dedicated. This is the first of a group of hospitals planned for construction. It was built at a cost of $300,000, and has an endowment fund of $600,000. Dr. M. Louise Lefort of New York, who has been in charge of the temporary hospital, will be in charge of the permanent hospital for the next two years.

Medical Advertising.—Surgeon General Cumming, of the United States Public Health Service, presided over a recent meeting called by the National Health Council, and held in the Metropolitan Life Insurance Building. The meeting was attended by many leaders in welfare and advertising, and resolutions were adopted aiming to stop fraudulent medical advertising, especially that promising cures for tuberculosis and cancer.

Sir Clifford Allbutt's Gifts to Cambridge Museum.—The Rt. Hon. Sir Thomas Clifford Allbutt, K.C.B., F.R.S., Regius Professor of Physic in the University of Cambridge, formerly a commissioner in lunacy, who died on February 22d last, aged eighty-eight, left an estate of the gross value of £56,963. He left to the Fitzwilliam Museum, Cambridge, his portrait by Sir William Orpen, and on the death of his wife, a quantity of antique furniture and drawings and paintings by noted artists, including Landseer, Crome, Romney, Rossetti, G. F. Watts, J. M. W. Turner, and Fripp. To Gonville and Caius College, Cambridge, his own college, he left three silver and gilt drinking horns, known as Swedish cups, requesting that his name as donor should be engraved thereon. He bequeathed fifty pounds each to the British Medical Benevolent Fund and the Medical Charitable Fund for the West Riding of Yorkshire.

Sydenham Hospital.—The cornerstone of the new Sydenham Hospital, at Manhattan Avenue and 123d Street, New York, was laid Sunday, May 17th. The Hon. Bird S. Coler delivered an address.

Postgraduate Course at Columbia.—Courses of three and six weeks' duration in public health, preventive medicine, and medicine, will be given at Columbia University from July 6th to August 14th.

Illinois Prenatal Work.—The state commissioner of health of Illinois has made arrangements for correspondence courses of instruction in prenatal care. Practical questions in preventive problems will be answered by qualified physicians.

Postgraduate Instruction.—The University of Minnesota School of Medicine and the state medical society have adopted a plan for postgraduate instruction, whereby clinicians will be sent to selected rural points one day each week for thirteen weeks.

Anniversary of Women's Medical College.—The seventy-fifth birthday of the Women's Medical College of Pennsylvania will be celebrated June 3d in Philadelphia. Starting with forty students, there are today fifteen hundred alumnæ. This is the only women's medical college in the United States.

Dinner to Doctor Howe.—Dr. Lucien Howe, of Buffalo, New York, was guest of honor at a dinner celebrating his fiftieth year in the practice of medicine. A silver loving cup was presented to him. Among the speakers were Dr. George deSchweinitz, of Philadelphia, and Dr. James W. Putnam and Dr. F. Park Lewis, of Buffalo.

Study of Public Health Activities.—Dr. James A. Tobey, recently of the National Health Council, is conducting a study of federal public health activities, for the Institute for Government Research of Washington. A preliminary study shows at least twenty-six bureaus or branches of the federal government interested in public health work.

Memorial at Cathedral.—A fund is being collected to erect a bay with stained glass windows in honor of St. Luke in the Cathedral of St. John the Divine, New York. Sculptural figures of great healers and illustrations in stained glass of great events in medical history will be used in decoration. Dr. John Bentley Squier, Jr., of New York, is chairman of the division for the medical profession.

Medical Arts Building.—A new twelve story building in Oklahoma City has been opened, with about forty per cent. of the physicians and dentists of the city occupying offices. It is expected that eventually the building will be tenanted entirely by members of these professions. The Oklahoma County Medical Association's library is also in the building.

Hebrew University Campaign.—A campaign for one million dollars for the medical college and hospital of the Hebrew University, Palestine, has been started. A meeting of the American Jewish Physicians' Committee was recently held in New York, with Dr. Samuel J. Kopetzky presiding. Dr. Nathan O. Ratnoff is president of the committee and Dr. Emanuel Libman, treasurer.

Iowa Medical Library.—Pending construction of the new medical laboratory building of the Iowa State University, which will provide space for a library of 75,000 volumes, the medical books of the university have been collected and housed in the old chemistry building. The library has been increased by the collection of the late Dr. Pick, psychiatrist of Prague—some six thousand volumes.

Red Cross Memorial.—The Emergency Canteen of the American Red Cross, at a New York meeting, has voted fifteen thousand dollars for the endowment of a memorial room in the New Presbyterian Hospital. Dr. Thomas W. Salmon, one of the speakers, urged that the room be devoted to the care of mentally disabled war veterans. More than ten thousand dollars was subscribed on the day of the meeting.

Exchange of Scientific Publications.—The Russian Information Bureau in Washington is representing the Joint Information Bureau of Moscow in an endeavor to facilitate regular contact as well as an exchange of scientific periodical and nonperiodical publications between interested institutions, groups, and individuals of the Soviet Union and this country. Personal exchange of work between scientists engaged in similar research activities could be arranged as well as the publication of manuscripts and articles in the general periodical and special press. Information may be obtained from the Russian Information Bureau, 2819 Connecticut Avenue, N. W., Washington, D. C.

New Fellowship.—A fellowship in experimental medicine at the University of Cincinnati, which will provide six hundred dollars a year for three years, is to be established through the generosity of Dr. and Mrs. Alfred Friedlander.

Reunion of Medical Officers.—A dinner will be held May 27th at the Ritz-Carlton Hotel, Atlantic City, as a reunion of medical officers serving in the world war. Tickets may be obtained from Colonel Burt R. Shurly, 62 West Adams Avenue, Detroit, Michigan.

American Academy of Physiotherapy.—This society will hold its midyear meeting at Atlantic City, Monday and Tuesday, May 25th and 26th, at the Chalfonte-Haddon Hall. There will be a session devoted to miscellaneous subjects, one on ultraviolet therapy, and one on electrosurgical methods.

American Proctologic Society.—The American Proctologic Society will hold a meeting at Atlantic City, May 25th and 26th, at the Ambassador Hotel. The four sessions will be devoted to anesthesia in rectal surgery, anorectal fistulæ, hemorrhoids, and cancer of the rectum. Dr. Frank C. Yeomans, of New York, will deliver the presidential address.

Personal.—Dr. Florence Sabin has resigned as professor of histology at Johns Hopkins Medical School, in order to devote her time to a further study of blood cells at the Rockefeller Institute. Doctor Sabin was recently elected a life member in the National Academy of Sciences, the first woman so honored.

Dr. George Miller MacKee of New York has resumed personal charge of his practice after a long absence.

Dr. David E. Hoag, who for several years has been lecturer in the department of Nervous and Mental Diseases at the New York University and Bellevue Hospital Medical College, has been made clinical professor.

Dr. Perry G. Moore, of Wabash, Indiana, was presented a watch by members of the Wabash Medical Society, to commemorate his eightieth birthday. Doctor Moore has been in practice fifty-nine years.

Dr. Samuel T. Darling of Baltimore is at the head of an expedition sent out by the Rockefeller Foundation, for the study of malaria in the Mediterranean countries.

Dr. William H. Walsh of Philadelphia has been appointed executive secretary of the American Hospital Association, succeeding the late Dr. Andrew R. Warner. Doctor Walsh formerly held this position, resigning at the time of the war.

Dr. Meyer A. Rabinowitz, visiting physician to the Jewish and Greenpoint Hospitals of Brooklyn, has gone to Europe four months, during which time he will visit the leading medical centres.

Dr. William Visher of New York has been appointed associate attending urologist at the Daughters of Jacob Home for the Aged.

Prof. E. Kraepelin, director of the Munich Research Institute for Mental Diseases, and Prof. F. Plaut, director of the Serological Department of the Institute, are in America studying the psychoses of the negro and Indian from the viewpoint of comparative psychiatry. They will spend some time at the Government Hospital in Washington.

Dr. James B. Murphy of the Rockefeller Institute has been elected foreign member of the *Deutsches Zentral-Komitee zur Erforschung und Bekampfung der Krebskarankheit*, of Berlin.

Dr. Daniel H. Eisendrath of Chicago read a paper on Strictures, Kinks, and Abnormal Ureteral Insertions as Causes of Abdominal Pain, before the New York Academy of Medicine.

Dr. William P. Healy of New York spoke on Carcinoma of the Uterus, Treatment by Irradiation, at the joint meeting of the New York and Philadelphia Obstetrical Societies, recently held in Philadelphia.

Dr. Louise Pearce, of the Rockefeller Institute, has been elected a Fellow of the Royal Society of Tropical Medicine and Hygiene.

Dr. E. A. Balloch, professor of surgery in the Howard University School of Medicine, of Washington, D. C., who has been on its faculty since 1880, was recently honored by a testimonal dinner given by the Howard Medical Reading Club of New York.

Dr. Arthur C. Strachauer, of the University of Minnesota Medical School, has become director of the new George Chase Christian Cancer Institute of the University, a research institute and fifty-bed hospital donated by Mrs. George Chace Christian.

Foreign Correspondence.

LONDON LETTER

(From our own correspondent)

London, *March 27, 1925.*

HARNESSED RADIUM

According to Mr. Courtauld, speaking when presiding at an annual court of the governors of the Middlesex Hospital, remarkable results have been obtained in the tests to capture radium. He declared that the emanations from radium had been captured, purified, condensed and bottled in tiny tubes and the Middlesex Hospital was now in a position to offer supplies to other hospitals. During the past few weeks the hospital had been testing with excellent results a new method for distributing radium for the treatment of disease. In the Radon Centre of the hospital emanations from radium had been bottled in small tubes. (For the sake of brevity, radium gas had been named radon.) To accomplish this it had been necessary to install an expensive plant. This the hospital had been able to do with the help of funds provided by the Medical Research Council which was also providing the means necessary to pay a part of the salaries of an expert staff and maintain the installation. Until it was proved possible to capture radon and bottle it for distribution, the Middlesex Hospital had been compelled in the interests of its important cancer wing and its extensive research work to husband its stock of radium and refuse to part with small doses, this in spite of the fact that it holds the largest individual stock of radium in the world. Now after exhaustive trial in its own hospital and in St. Bartholomew's, to which it had been sending two radon tubes a week, the Middlesex Hospital was in a position to supply these curative tubes to other hospitals. The possibilities for the treatment of disease by this new method of distributing and applying radium were very great. By capturing the gas which would otherwise be wasted it was now possible to multiply thousands of times the curative value of any given quantity of radium.

Stripped of technical details the method used in collecting radon was as follows: In a room at the Middlesex Hospital Radon Centre was a ray proof box containing flasks, each of which held a quantity of radium salt in solution. From one of these flasks a vertical glass tube conveyed the radon through a hole in the wall to another room containing apparatus, by means of which the gas was purified and condensed with the aid of liquid air. In its condensed form the gas was passed into minute glass tubes called seeds and resembling small beans. Each of these was sufficient for a dose, in other words, its power of giving out the gas again held good for a definite time. In order to estimate the value of each seed before it was sent out, or used in treatment, an extremely interesting radon balance had been designed, and could be seen in operation. Before the Middlesex Hospital dispensed its radium emanations it was therefore able to satisfy itself that the process of bottling had been successful and that the seed would do its work on arrival at its destination. These seeds were valuable in all cases in which radium itself would be used.

NEW HOSPITAL IN SUSSEX FOR WOMEN AND CHILDREN

On the occasion recently of the annual meeting of the governors of a new hospital for women and children at Brighton, a hospital officered entirely by women doctors, Dr. Mary Scharlieb, C.B.E., opened the new x ray department. The present premises of the hospital were only opened in August, 1921, but already there is need for extension from thirty to fifty beds and a preliminary appeal is being issued for $100,000 to enable another wing to be built.

WOMAN DOCTOR'S SACRIFICE

At the Infants Hospital, Vincent Square, London, an eleven months' old twin was in a wasting condition when received at the hospital and two months' treatment produced no improvement. It was then decided to try blood transfusion. The father was not available, the mother gave her blood but fainted and then the woman physician in charge volunteered. Three times in the course of ten days blood was transferred, the amount given in all being half a pint, and with each transfusion the baby put on weight, and has since improved enormously.

ROYAL FREE HOSPITAL NEW NURSES' HOME

Lord Riddell, the president of the Royal Free Hospital, London, the hospital of the Medical School for Women, on March 27th opened the Alfred Langton Home for Nurses attached to the hospital. Lord Riddell announced that the home was opened free from debt. The whole cost of building and equipment totalled $210,000, but the amount has already been secured by funds specially raised, towards which Mr. Langton has been a generous contributor.

THE SKULL OF BRUCE

Sir Arthur Keith, the curator of the Royal College of Surgeons and one of the greatest anatomists and anthropologists, has been writing recently on the characters of skulls. In this article he refers to a recent pronouncement by Prof. Karl Pearson to the effect that the human skull has a language of its own; one which it is hard to decipher. After centuries of endeavor we can construe only its simpler hieroglyphics: Yet we do continue to improve, and our progress justifies the belief that the day will arrive when a rational craniology will become the handmaid of biography. Both Prof. Karl Pearson and Sir Arthur Keith have been writing their views on the skull of King Robert Bruce, a cast of which is in the museum of the Royal College of Surgeons, where it is placed cheek by jowl with that of Robert Burns. Sir Arthur Keith and Prof. Karl Pearson reached their conclusions by different methods, yet the main conclusions reached by each are in agreement. The skull of the Bruce has characters of the most outstanding kind, chief of which are the rugged robustness of its face, the outstanding ridges over the eyes, the enormous width across the face from jowl to jowl, and the strength of the jaws. He was bull necked as is plainly indicated by the extent and strength of the bony platform on the base of the skull whereto the neck is fixed. Such an extensive platform signifies large and strong muscles in the neck, and such muscles in the neck require equally strong muscles in the spine and body. There is in the museum of the Royal College of Surgeons a rib of King Robert; it is the ninth of the left side. It had

been broken in some mischance which had befallen the king, but had healed well and soundly. The rib shows him to have been a big chested man; one we should expect to have a relatively long body; and yet his thigh and leg bones were not long. Professor Pearson finds that their dimensions answer to those of a man about five feet six inches in height. Bruce may well have been one of those men who seem tall when seated and yet of medium height when standing up, in which case we may add two or three inches to the estimate given by Professor Pearson. Sir Arthur Keith asks of what race was Bruce? Professor Pearson following tradition looks upon him as a hybrid between Norseman and Celt and adds, "He was able by Celtic imagination with a certain dash of slimness to win the Scottish nation to his side, and by aid of Nordic physique and persistency to be triumphant over his enemies." Sir Arthur Keith says that this statement might well be a quotation from the speech of a political historian but it certainly is not the language of craniology. The term Celt has been applied to diverse breeds of men, but Bruce's cranial type is not prevalent in any of them. Nor is it a type which is found in Saxon or Danish graveyards, although samples do occur in the Frankish burials of the north and west of France. Bruce's skull has more in common with what has been named by British anthropologists in recent years the beaker type than with any other known to the writer. Men with this type of skull began to take up their habitation along the eastern coasts of Britain in the second millennium B.C. They are known as "beaker" men because of the peculiar kind of earthenware vessel buried with them. Before they appeared in Britain they had penetrated to Baltic lands and spread southwards into France. Bruce's ancestry may have acquired the beaker blood in Baltic lands, in France or in Cleveland, where the type still persists.

LATIN AMERICA LETTER

(From our own correspondent)

Balboa Heights, C. Z., *April 15, 1925.*

GENERAL IRELAND VISITS CANAL ZONE

Surgeon General Merritte W. Ireland, United States Army, recently made an inspection of the sanitary and health conditions of the Canal Zone. He visited the hospitals and health offices to note the methods of administration, the quarantine stations, the Palo Seco leprosy colony, and the various army posts on the Zone. He was particularly pleased with the methods of sanitation including the mosquito control and the sewage and garbage disposal systems. He also visited the cities of Colon and Panama where the sanitary work is under the control of the Health Department of the Canal Zone.

HOOKWORM DISEASE IN PANAMA

Thanks to the energetic campaign of the Rockefeller Foundation, hookworm is being stamped out of Panama. The school children are learning about this intestinal parasite and how to avoid it. Better sanitary conditions are being installed. As a result of the campaign the Panaman native is being emancipated from this evil which has held him down helpless for decades and which has given him a name he does not deserve. Dr. Louis Schapiro, of the Foundation, who has charge of the work in Panama, said recently that a great deal of educational work was being done throughout the entire Republic of Panama, especially in the remote districts. He expressed the belief that it would not be long before the natives of all the villages would have been given treatment and educated in the control of the disease.

NOTED JAPANESE SCIENTIST VISITS CANAL ZONE

Dr. J. Hatori, biologist of the Institute of Science and Chief Health Officer of the Island of Formosa, Japan, recently stopped at the Canal Zone en route to the United States where he will visit the principal cities for the purpose of observing municipal health administration. He has recently completed a tour of South and Central America for the same purpose. Dr. Hatori is interested in certain problems of the United States Public Health Service, such as Rocky Mountain spotted fever, tularemia and other diseases transmitted by ticks and insects. He will spend a certain amount of time in the Bitter Root Valley of Montana, collecting ticks which transmit the spotted fever. While in Panama he made a collection of red bugs in order to find out if these are the same specie that cause the tsutsugamushi fever of Japan. While in the United States he will visit the hygienic laboratory of the Public Health Service and also the Army Medical School.

VETERAN CARE IN THE CANAL ZONE

To facilitate the hospitalization of claimants on the Isthmus, entitled to consideration under the World War Veterans' Act of 1924, the director of the Veterans' Bureau by letter of February 17, 1925, has vested the Governor of the Panama Canal with the following authority:

Authority is hereby vested in the Governor or the Acting Governor of the Canal Zone to extend medical and hospital treatment to U. S. ex-service men who it is believed after an examination, which should be made in each case, are in need of such treatment.

This service will be extended only to World War Veterans, and to veterans of any war, military occupation or military expedition since 1897, not dishonorably discharged, without regard to the nature or origin of their disabilities, provided that preference to admission to any government hospital for hospitalization under the provisions of this subdivision shall be given to those veterans who are financially unable to pay for hospitalization and their necessary travelling expenses.

This authority is based on Section 202 (10) of the Act of June 7, 1924, and the persons entitled to the benefits thereunder who require hospitalization or who desire information relative to such service should apply direct to Surgeon C. P. Knight, Chief Quarantine Officer of the Panama Canal, who is hereby appointed to handle the Veteran Bureau work under the direction of the Governor.

SAILORS MADE ILL FROM FOOD POISONING

More than 200 sailors were recently made suddenly ill at the Naval Submarine Base at Coco Solo, Panama, from spoiled food. Some were taken to the Colon Hospital, while those less seriously affected were treated at the Base by the Naval Medical Officers. No fatalities resulted but many of the men were extremely ill. The attack came suddenly and within a comparatively short time many cases were admitted to the hospital. Men on pass were stricken and taken to the hospital. At the base out of a company of sixty marines fully two thirds of them were stricken at the same time. Sailors who were ill de-

clare that the illness was caused by boiled tongue. It is understood that the men who did not eat the tongue were not affected in any way. An investigation has been ordered by the Commanding Officer but the results are not yet known.

CHILD HEALTH ACTIVITIES

The Mothers' Association of the Canal Zone held its regular monthly meeting the first Friday in April at Balboa. A health centre in Pedro Migel has been attended to overflowing the last two sessions. This makes the fourth health centre in operation on the Zone.

WEIRD CRAFT ARRIVES IN CRISTOBAL

The ship *Arcturus* bearing a scientific expedition bound for the Sargasso Sea and the Island of Galapagos in charge of Professor William Bebee, explorer and naturalist, arrived at the port of Cristobal the early part of April. After a few months in the Sargasso Sea the *Arcturus* will return and transit the Canal, proceeding to Galapagos where Professor Beebe will continue certain researches which were started over a year ago. This vessel is fitted out with a more wonderful and fearful equipment than any previous seagoing craft carrying a scientific expedition. A large laboratory has been built forward of the bridgedeck, tanks have been installed to keep fish alive as well as cages for wild animals, birds and reptiles. All appliances for dredging and trawling are installed and the ship has on board a dozen small boats with glass bottoms.

EXCLUSION OF UNDESIRABLES FROM CANAL ZONE

The Governor of the Panama Canal has recently issued an amendment to the immigration regulations governing the right of undesirable persons to enter the Canal Zone. The text of the order follows:

The Division of Quarantine shall be charged with the exclusion of undesirable persons at any time that cause for such exclusion shall come to their knowledge whether at time of entry of such person or subsequent thereto, if they shall find, after hearing that such person comes within any of the classes to be excluded: but in no case shall they act for causes arising subsequent to entry.

An order for the deportation of any person may be made by the Governor at any time that it shall be made to appear to him after hearing before the Police and Fire Division, that such person is undesirable from any of the causes mentioned in such acts and executive orders, by certificate of such hearing and finding by the said Fire and Police Division: provided, that in all orders of deportation the Governor shall set forth the finding on which the order is based."

Detention for inquiry as to the status of any person may be made by the Police and Fre Division on complaint of the Division of Quarantine and in construing this order the word "exclusion" as used herein shall mean the keeping out or putting out of a person for any disability within the meaning of the Act of Congress or Executive Order, which would bar entry and would continue as such until it becomes known and acted upon.

Deportation shall mean the eviction from the Canal Zone of any person who shall have entered with a lawful right but because of conduct or other cause arising after entry has become an undesirable within the meaning of the act."

When a person coming within any of the undesirable classes shall arrive at a Canal Zone port and shall desire to cross the Canal Zone in transit to another country, the agreement in writing required under the Executive Order from the owner, master or agent or interest controlling the vessel shall be secured by the Quarantine Officer."

VITAL STATISTICS OF THE CANAL ZONE

A total of 146 deaths occurred during the month of February, 1925, among the population of the Canal Zone, and the cities of Panama and Colon, which is equivalent to an annual death rate of 14.05 per thousand. The leading causes of deaths were: Tuberculosis (various organs), twenty-nine; pneumonia (bronchial and lobar), fifteen; cancer (various organs), eleven; nephritis (acute and chronic), eleven; diarrhea and enteritis (including colitis), ten. There were eight deaths from apoplexy and four from organic diseases of the heart. Of the total deaths, fifty, or thirty-four per cent., occurred among children under five years of age. There were eleven deaths among nonresidents of the Isthmus; these are not included in the above statistics.

There were 298 live births reported during the month, and twelve stillbirths. Including stillbirths, this is equivalent to an annual birth rate of 29.84 in 1,000 of population. Deaths among children under one year of age numbered thirty-three, giving an infant mortality rate of 110.74 in 1,000 live births.

The total number of malaria cases reported during the month was 102. Of these, nine were reported from Panama City, four from Colon, thirty-five from Canal Zone sanitated areas, and fifty-four originated outside of our sanitated areas. Of the total, eleven were employees, fifty were nonemployees, and forty-one were Army and Navy personnel. There were two deaths from malaria.

MOSQUITO CONTROL EXTENDED IN THE CANAL ZONE

Bearing in mind that the coming rainy season will bring a great addition of anopheles mosquitoes, the Health Department is extending mosquito control this year further than it has for several years past. The former boundary for ditching and draining was one mile beyond a thickly settled area, but this has been increased to two miles. Dr. C. P. Curry, in charge of the Division of Sanitation, has placed a large crew of laborers in old Panama on the Pacific side and also beyond Colon on the Atlantic side making new drains to take care of the extensive rains contemplated within the next few weeks. While the present death rate from malaria cannot be compared with that of construction days, this disease is still a menace to the employees of the Panama Canal, and every effort is being made to keep the death rate as low as possible.

ALASTRIM IN JAMAICA.

Weekly reports to the Chief Quarantine Officer of the Canal Zone show that alastrim is still prevalent in Jamaica. This disease is thought to be a mild form of smallpox and is controlled by vaccination the same as smallpox. Besides in Jamaica alastrim has been discovered in other countries too, Africa and Brazil. The authorities of Jamaica think that it is a distinct disease, but Dr. M. J. Rosenau, of Harvard University, gives the opinion that alastrim is simply modified smallpox, and he gives the following reasons: First of all smallpox is a disease which presents mutations and varies more than any other disease. The main thing from the viewpoint of prevention is that vaccination for smallpox also prevents alastrim. Alastrim, like smallpox, can never be controlled in Jamaica until universal vaccination is accomplished.

Book Reviews

RHEUMATIC HEART DISEASE

Rheumatic Heart Disease. By Carey F. Coombs, M. D., F. R. C. P., Lond. With an Introduction by F. J. Poynton, M.D., F.R.C.P., Lond. New York: William Wood & Co., 1925.

Few if any books that treat of heart disease portray the natural history of the several cardiac affections. They content themselves with describing various episodes in the evolution of the cardiac disorders. The student is left with a clear picture of endocarditis, pericarditis, myocarditis, cardiac insufficiency, each as a separate entity, but with little realization of the fact that all of these processes are, or may be, different phases of the same disease process in one person.

Not alone is rheumatic heart disease one of the most serious and frequent of all cardiac affections, but it presents itself to the clinician in a most variegated clinical picture. Dr. Coombs has performed a real service in writing this monograph which has as its central thesis the fact that rheumatic fever is an infectious disease which invades the whole body, and which, attacking the heart, may manifest itself in a multitude of ways, and with diverse physical signs and symptoms. Furthermore, he writes with authority, and with the knowledge of one who has been a student of the subject for many years.

There are a number of Dr. Coombs's conclusions with which most American cardiologists will be inclined to disagree. He accepts the streptococcus of Poynton and Paine as the proved cause of rheumatic fever, and he suggests that subacute infective endocarditis may be caused by the same organism. We do not see forms of scarlatinal carditis whose lesions are identical with those of true cardiac rheumatism. The author holds that mitral stenosis is always caused by rheumatism. This is certainly an exaggerated statement, for while it is true that rheumatism is most often at fault, instances of true arteriosclerotic narrowing of the mitral valve have been described, not infrequently, and verified at postmortem.

The chapter on pathology in which Dr. Coombs attempts to show that the specific lesions of rheumatism are the same in the myocardium, epicardium, valves, subcutaneous nodules is very interesting, and is illustrated with many original microphotographs. The illustrations are not always so clear and convincing as one might wish as evidence in a controversial subject. The weight of present opinion is certainly against the view that the specific Aschoff nodules arise from the intimal vascular endothelium, for they seem to develop first in the adventitia of the bloodvessel.

The most valuable section is the one on prognosis. Dr. Coombs was able to follow up a series of over six hundred cardiac cases after a maximum interval of fifteen years, and he formulated his conclusions from a study of this series of cases. This is a unique contribution to the subject of prognosis. He found that of one hundred patients who, when first seen, showed signs of definite rheumatic heart disease, recovery occurred in thirty-one, death ensued before the age of twenty in twenty-eight, before the age of thirty in thirty-eight, and before the age of forty in fifty patients; those who survived the age of forty though crippled, numbered nineteen. The highest incidence of fatalities is in the second decade.

DIAGNOSIS

Physical Diagnosis. By W. D. Rose, M.D. Fourth Edition. Three Hundred and Nineteen Illustrations. St. Louis: The C. V. Mosby Company, 1924.

The fourth edition of Rose's well known and deservedly popular work has been revised by the addition of new, and the elimination of old, illustrations and by minor alterations in the sections on graphic registration of the heart beat, on myocarditis, and on aortitis.

The bulk of this work is taken up with the clinical anatomy and physical signs of the respiratory and circulatory organs, and with the examination of the abdomen and viscera. There are additional chapters on the head, neck, and extremities, and on the nervous system. Where so much is given and so well, it may seem captious to find fault with the necessarily inadequate presentation of the physical examination of the eye, ear, and accessory nasal cavities, as well as the omission of some practically important details of the special application of clinical radiography.

Most of the illustrations are excellent, both instructive and technically fine. This does not, however, apply to the representations of x ray plates, some of which are so cloudy or so badly printed as to be of little value.

SURGERY

Operative Surgery. By J. Shelton Horsley, M. D., F.A.C.S. Second Edition. With 666 Illustrations. St. Louis: C. V. Mosby Co., 1924. Pp. 784.

This is a splendid book to have in association with other works on operative surgery. It is not a complete work taking in all types of surgery but one in which unusual operative procedures or later developments can be looked for. For instance, in the second edition the following new subjects have been brought up: "Among the interesting new operations described in this edition—none of which, so far as I am aware, has heretofore appeared in any surgical textbook or monograph—are the following: The lymphaticostomy of Costain for diffuse septic peritonitis and late obstruction of the bowels the operation of Stookey for innervating paralyzed muscles; the pylorectomy of Finney; the pulmonary lobectomy of Evarts A. Graham; the valvotomy of Cutler for mitral stenosis; the operation of Coffey and Brown for angina pectoris; the chordotomy of Frazier, and the intestinal resection of Kerr. This latter operation, when applied to resection of the cecum and right colon is, in avoiding infection, so superior to the technic I devised for removing this segment of the large bowel that I have abandoned my operation and adopted that of Kerr. The operations of Crile for partial lobectomy of the thyroid and ligation of the superior thyroid arteries are fully described. The technic of gastroenterostomy without clamps is given. A modification of the Billroth operation for partial gastrectomy is described. Two new procedures are included

in the chapter on plastic surgery. Many other less important changes or additions have been made."

The author has a clear and lucid manner of describing operations. He is wise enough to give the disadvantages as well as the advantages of the various descriptions. Many of the illustrations are photographs and photomicrographs of real clinical cases which add to the value of the work. The part devoted to plastic surgery is well written and illustrated and is of great value.

Dr. Horsley's work on the stomach is particularly interesting, as it describes in full his own operation, which has recently received a good deal of approbation. He also describes with very good illustrations the latest operation of Finney, which is a pylorectomy in which the stump of the stomach is sutured to the side of the duodenum making an end to side union. This is in reality a Polya with the duodenum used instead of the jejunum. The difficulty of this operation for the general surgeon is in the free mobilization of the duodenum. This is done by incising the peritoneum along the inner side of the duodenum from the stump of the duodenum lower down for a distance of about three inches below the level of the head of the pancreas.

The reviewer can thoroughly recommend this work for one who wishes information concerning the newer operations which are not in the ordinary works of surgery.

GYNECOLOGY

Gynecology. Medical and Surgical. By P. Brooke Bland, M.D. With 644 Illustrations, including forty-three colored text figures and twelve insert plates, ten of which are in colors. Philadelphia: F. A. Davis Co., 1924.

The reviewer feels that this is one of the best works combining both medical and surgical gynecology that he has had the privilege of reading. The author has a clear style, classifying his subjects in a systematic manner and supporting many of his statements with statistics. He shows remarkable knowledge of the literature. The part on sterility is particularly praiseworthy, as he goes into the sociological, the physiological and the pathological causes. The sections on surgery are clear and unbiased, clearly described, and adequately illustrated.

As a textbook and as a book of reference this is a thoroughly admirable work. The index is complete and well subdivided, so that it is easy to look up any particular subject.

THE INTESTINE

Nouveau Traité de Médecine. Fascicule XIV, Appareil Digestif (Intestin). Paris: Marson et Cie, 1924. Pp. 579.

This volume represents the authoritative French work on the intestine. The material is presented under six heads: 1. Pathology of the Intestine by Tremolieres and Caussade. This is much more than pathology in our narrower sense and includes etiology, symptomatology, diagnosis and treatment—in short a complete clinical study. 2. The gastrointestinal affections of infants by Nobecourt. 3. Intestinal Worms by Joyeux. 4. Ankylostomiasis by Perroncito. 5. Semiology of the Feces by Gaultier. 6. Pathology of the Rectum and Terminal Colon by Bensaude.

The book is well edited and the material well arranged. The illustrations are good, the colored plates of pathological specimens being really splendid. However, the x ray reproductions are not up to our standard.

As in other French works, one notes the absence of important allusions to the work of non-Gallic writers. This, however, is more of a loss to French readers than to us. More important and less understandable is what looks like carelessness in omitting an index. Why, after all, should not French books be made as accessible to rapid reference as books in other languages?

BACTERIOLOGY AND SEROLOGY

Manuel Technique de Microbiologie et Sérologie. Par le Professeur A. Calmette, S.-Directeur de l'Institut Pasteur, L. Nègre et A. Boquet, chefs de laboratoire à l'Institut Pasteur. Paris: Masson et Cie., Editeurs. 1925. Pp. 568.

This admirable technical manual from the hands of Professor Calmette and his assistants contains a very full survey of bacteriology and serology. It makes no pretensions to style, and is written in the usual laboratory jargon. It contains a good deal that is not in the ordinary bacteriological textbooks, such as the methods for obtaining cultures from various cavities of the body, directions for making vaccines, toxins, and antitoxins, and for checking them. There is also a section on the destruction of parasites of animals, and the general procedures of disinfection. These are valuable in any laboratory where the keeping of animals free from such infestation is an important part of their care. For those who read French this book is a useful addition to laboratory technic.

THE CHILD MIND

Vom dichterischen Schaffen der Jugend. Neue Beiträge zur Jugend forschung. By Dr. Siegfried Bernfeld, Quellenschriften zur seelischen Entwicklung, No. III. Leipzig, Wien, Zürich, Internationaler Psychoanalytischer Verlag, 1924. Pp. 285.

This book is offered as a preliminary study in a field as yet almost unexplored and of dimensions so vast that there can be only suggestion here of the opportunity both for psychological and literary investigation. Extracts are presented illustrative of the variety of material which comes under consideration. There are the immature expressions of the young child or the profuse but formless utterances of slightly later years; there are the better developed stories of later adolescence, in which the "tertiary," more objective elaboration of the simpler self expression is already taking place; there are examples of early literary efforts from some writers who have later found a place in literature; there is material also from the phantasy of children manifested in the fictions of play rather than committed to writing. The author's purpose is not to show exclusively or primarily the beginnings of literature; it is to bring before consideration the nature and content of these outpourings of children and adolescents, particularly as they take written form. This latter happens far oftener than would be revealed by later literary careers. For much of this output has no literary merit as such nor does it indicate a special inclination toward continuance in writing. Neither, the author notes, is writing a spontaneous means of expression for all children; some find expression for their infantile and adolescent complexes and aspirations in

this way; many do not. Only lightly has the author touched upon the revelation of complexes and strivings in the material examined. His purpose at first is only that of making a beginning in the collection and setting forth of material: the time for interpretation will come later.

CHILD PSYCHOLOGY

Safeguarding Children's Nerves. A Handbook of Mental Hygiene. By James J. Walsh, M.D., Ph.D., Sc.D. With a Foreword by Honorable Herbert Hoover. Philadelphia and London: J. B. Lippincott Company, 1924, pp. ix, 272.
